Chapter 1

Our sun and the stars

1.1 Introduction

The stars that populate our universe are all based on the same basic physical setup. There are a few types which are called stars, but aren’t stars according to the definition of stars as “a concentration of gas in space which generate a power output due to thermally ignited nuclear fusion at its core”. Among these are white dwarf stars, which are the cooling stellar cores left over from a powerful blast that has ejected the outer layers of the progenitor star. Brown dwarf stars are another example, but brown dwarfs are failed stars that are not able to generate enough heat and pressure in their cores to ignite nuclear fusion, and so are doomed to radiate the energy from the compression of their progenitor gas cloud and the radioactive elements in their interiors. In these notes we will deal only with “real stars”.

Stars have a heat generating engine in their central regions. The energy and heat is produced through nuclear fusion of light elements into heavier ones. That process is possible because the energy per nuclear particle needed to bind protons and neutrons together into an atomic nuclei, is lower and lower the heavier the nuclei becomes. That makes it energetically advantageous to fuse light elements, and the only reason this does not happen all the time, is that atomic nuclei have a strong repulsion force that makes it very hard to get them close enough to each other for the fusion to begin. The fusion of lighter into heavier elements has a limit where it no longer is energetically advantageous. That limit is iron consisting of 56 nuclear particles. For heavier elements, energy is needed to join more protons or
neutron to the nuclei. The nuclear burning rates\(^1\) of the fusion between
different nuclei depends sensitively on temperature and pressure. The large
dependence on temperature comes from the thermal motions needed to over-
come the repulsion between two nuclei. The repulsion between two nuclei is
the consequence of both nuclei having a positive electric charge which has
to be overcome by the thermal motions. The larger the nuclei the higher
their charge, and consequently the Coulomb repulsion force becomes larger.
To overcome that force, higher and higher temperatures are needed for fu-
sion to happen. The burning of hydrogen into helium is most efficient at
lower temperatures, because it only involves hydrogen with one proton in
the nuclei, while heavier nuclei only fuses at higher temperatures because
they contain more protons in their nuclei, and so have a larger charge. The
consequence is that stars initially burn hydrogen into helium and when the
energy production starts to vain, the stellar core starts to contract, heat
up and then igniting helium that then fuses into heavier elements and so
on. Stars need to have larger and larger masses to be able to burn heavier
and heavier elements. Our Sun will only be able to burn Helium in its last
nuclear burning phase, and will not be able to burn significant amounts of
heavier elements. In order for a star to be able to burn the heaviest elements
and produce Iron (Fe), they need to be much heavier than the Sun - roughly
20 solar masses.

The energy produced by the fusion in the central parts of the star is
transported to the stellar surface by either electromagnetic radiation or by
the movement hot gas from the interior of the star to the stellar surface i.e.
convection. The transport of energy through radiation might seem strange,
since the density of the gas in stellar interiors are very high, but it turns
out to be effective enough. Convection is somewhat akin to what can be
observed in a pot of hot water on the stove just before it boils. Patterns
consisting of upwellings of hot water from below, and thin lanes of water that
has now cooled at the surface and is on its way back down to be reheated
in the bottom of the pot.

Our sun is an example of a rather quiescent medium size star, but which
includes all these elements. It has a nuclear burning core where the fusion
of hydrogen into helium provides the energy that is initially transported
by radiation the first two thirds of the solar radius, until the gas becomes
convective and the gas motions transport the bulk of the energy to the
surface where it is radiated into space.

\(^1\)“Burning” is often used in this context, even though it is actually nuclear fusion, and
not burning which involves the oxidation of other materials

\$Id: sun_and_stars.tex,v 1.10 2016/01/19 12:55:14 boris Exp \$
CHAPTER 1. OUR SUN AND THE STARS

There are stars that radiate more than a million times more energy than our sun, as well as stars that radiate much less. In general light stars radiate less energy, while heavy stars radiate more because heavy stars have higher pressure and temperatures in their centers, making the fusion more effective. It becomes so much more effective that the heavy stars are able to burn their available hydrogen much faster than light stars. Stars that are very light ($\sim 0.1M_\odot$) have a lifetime which is much longer than the present age of the universe ($\sim 13.7$ Gyr), while heavy stars can have lifetimes which is only a few hundred million years, compared to the estimated lifetime of our sun of roughly 13 Gyr.

At some point the fuel that is needed for the nuclear fusion at the core of an evolving star runs out, and the star is no longer able to resist the gravitational pull and it will contract. The contraction releases energy and for heavy stars a new fusion process is then able to start. For light stars, the contraction will not be able to start a new fusion process and the core will contract even more. The last part of a stars life depends heavily on their initial mass. Stars with masses around one solar mass will end up as a white dwarf star, which has ejected its envelope as a consequence of a last desperate attempt to ignite fusion in a ring around the old core where there are still enough hydrogen to be consumed by fusion. A white dwarf has a nucleus which resists gravity through quantum effects. The electrons are forced into such a small volume that the quantum rules for fermions makes it impossible to force more electrons into the same volume, because all available quantum states are already full. Heavier stars of more than roughly 8 solar masses will after a number of contraction and expansion phases turn into a super nova type II where the stellar core compresses into a neutron star where most protons and electrons have fused into neutrons, and resist gravity by the quantum exclusion principle for neutrons which are fermions like electrons. The explosion of a super nova type II are very violent, and is capable of fusing elements heavier than Iron when it happens. Almost all the elements heavier than iron found on earth is created through super novae type II.

1.2 Our sun

The sun is a quiescent middle of the road star of spectral type G 2V. Even though it might seem as a rather boring star, its energy output of $3.8 \times 10^{26}$ W is still quite remarkable. For comparison, the total energy output by the total nuclear arsenal of both the USA and the Soviet Union at the height
Figure 1.1: An image of the solar photosphere showing the imprint of the solar convection. Hot gas flows up from the solar interior creating the bright bubbles and the radiates their energy away, contracts and flows back into the solar interior in the dark lanes surrounding the bright bubbles. The image is taken with the Swedish 1-m Solar Telescope (La Palma, Spain) through a continuum spectral filter and is roughly 58 Mm on a side.

of the cold war of \( \sim 77000 \) nuclear warheads, is equivalent of the energy produced by the sun during \( 2 \cdot 10^{-5} \) s. The energy production in the core is dominated by hydrogen fusing into helium. The energy is transported from the core outwards by photons, which move a very small distance before they are absorbed, to be reemitted and traveling further out. At \( \frac{2}{3} \) the way to the surface, the gas becomes convectively unstable, and starts to overturn, creating large rising convective cells of hot gas, that travels to the surface where it cools by radiating its energy into space. When the gas becomes cool enough its density has increased enough that it starts sinking back into the solar convective region. That creates a granular pattern on the surface.
of the sun as shown in Fig. 1.1.

Other stars do not show the same structure. The heaviest and most luminous stars rely on radiative transport only, while certain classes of low mass stars have convection from the nuclear burning core, all the way to their surface. Some stars even have multiple convective layers sandwiched between radiative layers.

1.3 These notes

These notes are supposed to be a brief introduction to stellar interiors and the physics that control the structure and evolution of stars. The notes are very brief, and is build upon a number of classics text books, which will not be cited directly, but interested students might find more information and deeper explanations on some of the subjects touched upon here. The text books are: Stix: “The Sun”, von Mieses: “Mathematical theory of compressible fluid flow” and Schroeder: “An introduction to Thermal Physics”.

Chapter 2

Stars

2.1 The main parameters of stars

In this chapter we will derive very simple relations between the main parameters of stars, their mass, their radius and their energy output or luminosity. This can only be done under some quite strict assumptions, but as it turns out, these assumptions are very close to being correct. Some of the equations used here will be explained in more detail later in these notes.

The first assumption we make is that stars are spherically symmetric, which for most stars is not exactly correct. That is mostly due to their rotation, so that their radius along their rotational axis is smaller than perpendicular to their rotational axis. Most stars on the main sequence are not rotating that fast, and so they are very close to being rotationally symmetric. Our sun is flattened by less than 0.001%, even though its surface rotates with a velocity of roughly 2 km s\(^{-1}\). An important effect of this assumption is that we cannot treat convection in detail, since convection transports gas up and down along the radius of the star, but more importantly it also transports gas perpendicular to the radial direction, and that is in conflict with the spherical symmetric assumption as that means that velocity only depends on radius. Convection is treated in more detail in Sec. 5.3.

The second assumption we have to make is that stars are in hydrostatic equilibrium. That means that the pressure gradient at all locations are in balance with the gravitational force. This assumption again excludes a few types of stars form this treatment, since a few types of stars have large changes in radius and luminosity due to pressure and gravitational instabilities of which the most common type are called Cepheid stars.

A star in hydrostatic equilibrium has to be able to maintain a high
pressure at its core, but since it looses energy from its surface in the form of radiation, it would cool down and the high pressure at its core cannot be maintained, unless the star produces energy at its core. That happens through fusion of lighter elements into heavier ones, and independent of which elements are fused, the process is extremely sensitive to temperature. Pretty much all stars have the same central temperature because the energy production is so sensitive to temperature. The energy production rate through the CNO (see Chap. 3) is proportional to $T^{16}$, meaning that a very small change in temperature means a huge increase in energy production. A good approximation to the central temperature of stars is

$$T_c \approx 1.5 \cdot 10^7 \left( \frac{M}{M_\odot} \right)^{1/3} \text{ K}$$

To get to relations between the main parameters controlling stellar structure we can use the virial theorem. It states in this case that the potential energy of a star is roughly equal to twice the total kinetic energy of the particles in the star. The potential energy of a star is roughly

$$E_{\text{pot}} = \int \int \frac{G}{r} dm_1 dm_2 \sim \frac{GM^2}{R}$$

where $G$ is the gravitational constant, $r$ is the distance between mass 1 ($m_1$) and mass 2 ($m_2$). The kinetic energy of the particles in the star is roughly

$$E_{\text{kin}} = \frac{3}{2} N k_B T \sim \frac{M}{m_p} k_B T$$

where $N$ is the number of particles in the star, $k_B$ is Boltzmann’s constant, $m_p$ is the mass of a proton and $T$ is a typical temperature. By using these expressions and the virial theorem, we get a relation for the radius of a star

$$R \sim 10^{11} \left( \frac{M}{M_\odot} \right)^{2/3} \text{ cm}$$

when using cgs units. The radius of the sun is roughly $7 \cdot 10^{10}$ cm, so the relation is very precise considering we have neglected a number of constants along the way.

**Exercise 2.1:**
Show Eq. 2.4 using the expressions for the kinetic and potential energy, and calculate the numerical constant in Eq. 2.4 using SI units.
The other main characteristic of a star is the total energy it releases in the form of radiation. Energy from the core of a star moves slowly through the star until it reaches the surface, and then it is released into space. The released energy can be observed and the total energy released in the form of radiation is the stars luminosity \( L \). If the energy has difficulty moving through the star, then the energy is contained longer inside the star, and the amount of energy inside the star is therefore higher. Therefore the resistance to have energy being transported through the gas - called the opacity \( \kappa \) of the gas inside the star is important to know if we want to know the luminosity of a star. The opacity of a gas comes from atomic physics, and depends only on the ionisation degree and the atomic species present in the gas. If we assume it to be roughly constant for a star, then we can find the following relation

\[
\frac{L}{4\pi R^2} = \left( \frac{c}{\kappa \rho} \right) \frac{dU_{ph}}{dr}
\]  

(2.5)

where the left hand side is the flux of energy through the star (energy per area per second) and the left hand side is a diffusion constant involving the opacity and the gradient of the radiative energy. The energy of the photons is simply given as \( U_{ph} = a T^4/3 \) where \( a \) is the radiative constant, so we can now write the luminosity as

\[
\frac{L}{4\pi R^2} = \frac{ac}{3\kappa \rho} \frac{dT^4}{dr}
\]  

(2.6)

inserting values for \( \rho, T \) and \( R \) we find an expression that just says

\[
L \propto M^3
\]  

(2.7)

This expression also fits well with observations, and it shows that stars produce much more energy if they are heavy. Stars seems to be rather easy to understand, when looking at these expressions, and it should be surprising that using these simple expressions we actually find relations which hold. Remember that so far we have not looked at the atomic physics that control the energy production in the centre of stars and we haven’t looked at how the energy is transported through the star either. The energy production does not need to be fusion at all, and the transport of energy only needs to be describable as a diffusion process in order for these relations to hold. So stars are easy to understand - except the devil is of course hidden in the details, so the rest of this course will be to understand each of the processes involved in keeping a star alive and calculating how stars adjust.
their internal structure to be able to remain stable even though stars can have masses that span 4 orders of magnitude and luminosities that span more than 8 orders of magnitude.

**Exercise 2.2:**
Use Eq. 2.4 and Eq. 2.1 to derive Eq. 2.7. Using values for the sun, find the constant of proportionality in Eq. 2.7 and then use that constant to find the luminosity of stars with masses of $0.1M_\odot$ and $10M_\odot$. You can find constants you need in App. A and values for solar parameters in App. B.

**Exercise 2.3:**
Imagine a star that has mass $M$ and radius $R$ however its mass density has the following form:

$$\rho = \rho_c(1 - \left(\frac{r}{R}\right)^2) \quad (2.8)$$

where $\rho_c$ is a constant and $r$ is the distance from the centre of the star.

(i) Find $m(r)$. (ii) Find the relation between the total mass $M$ and radius $R$. (iii) Calculate the average density of the star (Hint: $\rho_{\text{aver}} = 0.4\rho_c$).

The internal pressure of a star can be found by looking at hydrostatic equilibrium. Here it is assumed that the pressure and the gravitational force is balancing each other, so that the star is stable and does not change its structure. The radial component of the force balance then means that

$$\frac{\partial P}{\partial r} = -\frac{Gm\rho}{r^2} \quad (2.9)$$

If we now assume that we can use the whole stellar radius as $\partial r$, then we get

$$\frac{P_c}{R} = \frac{GM}{R^2} \frac{M}{4\pi \rho R^3} \quad (2.10)$$

$$P_c = \frac{3G M^2}{4\pi R^4} \quad (2.11)$$

Inserting solar values we can see that this value is a bit too low, so if we believer that the sun is a good way to calibrate this equation, then we find

$$P_c = 3.45 \cdot 10^{16} \left(\frac{M}{M_\odot}\right)^2 \left(\frac{R}{R_\odot}\right)^{-4} \quad (2.12)$$
Chapter 3

Stellar engines

3.1 Introduction

The power that keeps the star alive and which is finally emitted as electromagnetic radiation at its surface is provided by nuclear fusion. The fusion happens in steps depending mainly on temperature. The efficiency of a certain process depends steeply on temperature and pressure because temperature can be converted into thermal motions, and fast motions makes it more probable for two nuclei to overcome the electrostatic repulsion and get close together. The fusion of heavier and heavier elements requires higher and higher temperatures which again requires larger stellar masses. A star will start by burning the element which produces the most energy when fused into another element. Fig. 3.1 shows how much energy is available when fusion happens. The curve shows the binding energy per nucleon for all the elements found naturally in the universe. The binding energy is the energy required to split the nuclei into free protons and neutrons. Naturally Hydrogen has zero binding energy because it consists of a free proton. Since it takes energy to split Helium, that energy must then be available when fusing Hydrogen into Helium. That energy is converted into free energy and ends up as heat. Fusion of elements releases energy as long as the nuclei going into the process has lower binding energy than the nuclei that is produced. Iron is then the last element that can be produced by fusion and release energy.

Exercise 3.1:
In the following we will assume that the particles in the nuclear burning centre of the sun are Maxwellian. That means that their velocity, and
Figure 3.1: The binding energy per nucleon. Binding energy is the amount of energy needed to split the nucleus apart into isolated protons and neutrons. (From Fastfission and Wikipedia)

Energy is distributed according to a Maxwell-Boltzmann distribution. In order for that to be true, it is necessary for the particles to have collided with each other a large number of times, before they are able to move to a region of the sun which has a different temperature (which is a consequence of the particle momentum distribution). The distance a particle can travel before it collides with another particle is called the mean-free-path.

To calculate the mean free path, imagine we have a cylinder in which a particle moves from one end to the other. The cylinder has a cross section of 1 cm$^2$. The cylinder is filled with protons at rest each with a mass of $m_p$ and they are placed uniformly so that they have a mass density equal to the average mass density of the sun (get mass and radius of the sun from App. B). The protons have a circular cross section with radius which is the Bohr radius $a_0$. Now imagine that you are trying to fire protons down through the cylinder without hitting the protons in the cylinder. You can imagine that the cross sections of the protons in the cylinder does not overlap and that there are no space between the...
3.2. THE P-P CHAIN

protons areas. How long can the cylinder be before the protons fill up the whole cross section of the cylinder?
Compare that length with the temperature gradient in the sun, assuming that it is constant from the solar centre to the solar photosphere. Is it a good assumption that the particles are Maxwellian?

Exercise 3.2:
At the surface of the sun (the photosphere) the scale height of the temperature is roughly 670 km, how does that compare with the mean free path of an atom using the same formula that you found in Exerc. 3.1? The density of the photosphere is about \( \rho = 2.1 \cdot 10^{-4} \text{ kg m}^{-3} \), assuming pure hydrogen gas for convenience.

3.2 The P-P chain

The Proton-Proton chain is the basic fusion between hydrogen nuclei. There are several different branches which have different end products or uses, but does not change, heavier elements. The three P-P chains have their own temperature dependence and they will all be described here. The three branches have the same reaction to begin with, and then branches of using different reactions to release energy. The first reaction in all three chains are the fusion of two hydrogen nuclei:

\[
\begin{align*}
^1\text{H} + ^1\text{H} &\rightarrow ^2\text{D} + e^+ + \nu_e + 0.15 \text{ MeV} \\
\end{align*}
\] (3.1)

The electron neutrino \( \nu_e \) produce in this reaction is very weakly interacting and pass through the sun without interacting, so the energy it possesses (0.25 MeV) is lost. This process is very slow, because it requires the decay of a proton to a neutron which on average takes a billion years for an individual proton. When the proton decays, a positron is necessarily created in order to satisfy charge conservation. The positron \( e^+ \) very quickly annihilates with an electron \( e^- \) and produces two photons \( \gamma \) which can be readily absorbed giving another 1.02 MeV. So the energy output from this reaction is

\[
Q_{pp} = 0.15 \text{ MeV} + 1.02 \text{ MeV}
\] (3.2)

The energy output from each of the following reactions can be calculated in a similar way, taking into account that neutrino energy is lost and remembering that if a positron is created, then it is necessary to include the annihilation energy too.
The second step transforms Deuterium into Helium:

\[
\frac{2}{1}D + \frac{1}{1}H \rightarrow \frac{3}{2}He + 5.49 \text{ MeV} \tag{3.3}
\]

These two steps are common to all there branches, but then there are three different ways to produce \( \frac{4}{2} \text{He} \).

**Exercise 3.3:**
Calculate how much mass disappears in the first two steps of the PP chains, by comparing mass input and mass output. How much energy does that correspond to? How large a percentage of the energy is lost due to the emission of the neutrino? How large is the difference in percentage between the numbers given in Eqs. 3.1 and 3.3 and the one you just calculated? Why?

**PP I branch**
The PP I branch is the most straight forward of the three PP branches. It directly converts \( \frac{3}{2} \text{He} \) into \( \frac{4}{2} \text{He} \):

\[
\frac{3}{2} \text{He} + \frac{3}{2} \text{He} \rightarrow \frac{4}{2} \text{He} + 2 \frac{1}{1}H + 12.86 \text{ MeV} \tag{3.4}
\]

This way three hydrogen nuclei is used to each \( \frac{3}{2} \text{He} \) which then fuses into \( \frac{4}{2} \text{He} \) and releases two \( \frac{1}{1}H \), all in all using four \( \frac{1}{1}H \) to produce one \( \frac{4}{2} \text{He} \). The PP I branch happens 69% of the time.

**Exercise 3.4:**
Calculate the energy emitted by the reaction \( \frac{3}{2} \text{He} + \frac{3}{2} \text{He} \rightarrow \frac{4}{2} \text{He} + 2 \frac{1}{1}H \)

**PP II branch**
The second and third proton-proton branch produce heavier elements in the intermediate steps, but they are all consumed during later steps in the branch:

\[
\begin{align*}
\frac{3}{2} \text{He} + \frac{3}{2} \text{He} & \rightarrow \frac{7}{4} \text{Be} + 1.59 \text{ MeV} \\
\frac{7}{4} \text{Be} + e^- & \rightarrow \frac{7}{3} \text{Li} + \nu_e + \delta E \\
\frac{7}{3} \text{Li} + \frac{1}{1}H & \rightarrow 2 \frac{4}{2} \text{He} + 17.35 \text{ MeV} \tag{3.5}
\end{align*}
\]

The step in the PP II branch involving an electron is an inverse \( \beta \)-decay, which produces free energy \( \delta E \) that depends on the initial energy quantum number of the produced \( \frac{7}{3} \text{Li} \) nucleus. In the relevant temperature range
where the PP II branch is effective, there is only two energy states the $^{7}_3\text{Li}$ can be in, the ground state and an excited state. The produced neutrinos consequently carry either 0.86 MeV or 0.38 MeV, depending on if energy is used to excite the nucleus of $^{7}_3\text{Li}$. About 90% of the time $^{7}_3\text{Li}$ is produced in the ground state, so that the neutrino energy is 0.86 MeV, while the last 10% of the time $^{7}_3\text{Li}$ is produced in the excited state and the neutrino energy is 0.38 MeV, giving a weighted average of 0.81 MeV. That energy is lost, because the neutrino does not interact with matter on its way through the sun, so on average that reaction leaves only $\delta E = 0.05$ MeV to the energy budget of the sun. The PP II chain happens 31% of the time.

**Exercise 3.5:**
Why is an electron neutrino produced in the production of $^{7}_3\text{Li}$?

**Exercise 3.6:**
The absorption coefficient per unit mass for a neutrino is $\kappa_\nu = 10^{-21}$ m$^2$ kg$^{-1}$. This absorption coefficient can be plugged into the equation for mean free path, but now using $l_{mfp} = 1/(\kappa_\nu \rho)$. Find the mean free path at the centre of the Sun for the neutrinos.

**PP III branch**

The PP III branch is not very effective in the sun. The PP III branch do not produce much energy unless the temperature is above 20 MK or the abundance of the heavy elements needed is much higher than in the sun. For the sun with a core temperature of less than 15 MK, it only produces roughly 0.1% of the total energy.

$$
\begin{align*}
{\frac {3}{2}}\text{He} + {\frac {4}{2}}\text{He} &\rightarrow {\frac {7}{4}}\text{Be} + 1.59 \text{MeV} \\
{\frac {7}{4}}\text{Be} + {\frac {1}{1}}\text{H} &\rightarrow {\frac {8}{5}}\text{B} + 0.14 \text{MeV} \\
{\frac {8}{5}}\text{B} &\rightarrow {\frac {8}{4}}\text{Be} + e^+ + \nu_e + 6.88 \text{MeV} \\
{\frac {8}{5}}\text{Be} &\rightarrow 2{\frac {4}{2}}\text{He} + 3.00 \text{MeV}
\end{align*}
$$

(3.6)

The positron created annihilates with an electron and provides the same energy as the positron created in the PP I chain. Step three requires $^8\text{B}$ to go through a radioactive $\beta$-decay to $^7\text{Be}$, and it produces very high energy neutrinos(7.2 MeV) that can be detected on earth and has been the source of the solar neutrino problem, where far fewer neutrinos were observed than the number dictated by solar models. It is now recognized that the neutrinos
from the PP III chain must go through a conversion on their way from the sun to the earth, so the solar neutrino problem first believed to be a problem for astronomers are now a problem for particle physicists instead.

**Exercise 3.7:**
For each of the PP branches, calculate how much energy is released in the whole branch (use the mass difference between what goes into the branch and what comes out) and calculate how much of that energy goes into neutrinos for each branch given as percentage of the energy produced in the branch.

**Exercise 3.8:**
The solar luminosity is $3.85 \cdot 10^{26}$ W, calculate how much mass the sun looses every second if the sun produced all its energy with the PPI chain. Assuming the solar luminosity is constant, calculate how long it takes the sun to burn one earth mass. Assuming that the solar luminosity is constant (a very unrealistic assumption here), how long does it take for the sun to convert all if its mass into energy.

**Exercise 3.9:**
Calculate the lifespan on the main sequence for a B - type star with $M_\star = 16M_\odot$ and $L_\star = 8000L_\odot$ and an M type star with $M_\star = 0.1M_\odot$ and $L_\star = 8 \cdot 10^{-4}$

**Exercise 3.10:**
Calculate the average energy released when 4 protons are fused into one $^4$He nucleus, taking into account all the PP branches and their using the fraction of the energy they produce in the Sun and how much they lose to neutrinos.

### 3.3 The CNO cycle

The CNO cycle uses Carbon, Nitrogen and Oxygen to produce Helium. The process is only effective at temperatures above $10^7$ K, so produces very small part of the fusion energy production in the Sun. There are a number of sub
branches of the CNO cycle, but only the dominant one will be shown here:

\[
\begin{align*}
\text{12}_6^6C + \text{1}_1^1H & \rightarrow \text{13}_7^7N + 1.95 \text{ MeV} \\
\text{13}_7^7N & \rightarrow \text{12}_6^6C + e^+ + \nu_e + 0.49 \text{ MeV} \\
\text{12}_6^6C + \text{1}_1^1H & \rightarrow \text{14}_7^7N + 7.55 \text{ MeV} \\
\text{14}_7^7N + \text{1}_1^1H & \rightarrow \text{15}_8^8O + 7.30 \text{ MeV} \\
\text{15}_8^8O & \rightarrow \text{14}_7^7N + e^+ + \nu_e + 1.75 \text{ MeV} \\
\text{15}_8^8O + \text{1}_1^1H & \rightarrow \text{12}_6^6C + \frac{3}{2}\text{He} + 4.97 \text{ MeV}
\end{align*}
\]

The neutrinos produced in steps two and 5 are both low energy neutrinos transporting away 0.71 and 1.00 MeV respectively. The other branches of the CNO cycle are only effective at much higher temperatures, so for instance the next most energy producing CNO cycle branch produces only 0.05% of the total energy produced by the CNO-cycle in the sun.

**Exercise 3.11:**
Calculate the mass deficiency of the CNO cycle and the energy released by it. How much (in percentage) is the energy lost due to neutrinos?

**Exercise 3.12:**
Calculate the energy needed as input for the reaction $\frac{3}{2}\text{He} + \frac{3}{2}\text{He} \rightarrow \frac{8}{4}\text{Be} + \gamma$.

**Exercise 3.13:**
Why does a positron provide 1.02 MeV to the energy? Do the calculation that shows that it is in fact 1.02 MeV. Where does the electron come from?

**Exercise 3.14:**
How many PP reactions take place in the Sun every second (remember how much energy is produced by each branch and assume that all branches produce the same energy as PPI)? The luminosity of the Sun is $3.85 \times 10^{26}$ W. How many neutrinos are produced in these PP reactions in one second?

### 3.4 Energy production rate

Fusion processes have at least one strong barrier it has to circumvent in order to be successful. The Coulomb repulsion between two positively charged
atomic nuclei makes it very hard for them to interact. Most “collisions” are not actually collisions, but just the Coulomb repulsion at work. In order for the thermal motions to be strong enough to overcome the Coulomb repulsion, the kinetic energy of the incoming atomic nuclei must be larger than the electrostatic potential produced by the other atomic nuclei. For hydrogen the electrostatic potential energy is just:

$$U_E = \frac{1}{4\pi\varepsilon_0} \frac{q_1 q_2}{r}$$  \hspace{1cm} (3.8)

where $\varepsilon_0$ is the permittivity of free space, $q_1$ and $q_2$ is the charge of the two particles involved, and $r$ is the distance between them. The potential energy is also the amount of work needed to overcome the potential, so by assuming that the particle comes from infinity and has to get within a distance of a proton radius, a rough approximation of how much kinetic energy a proton must possess in order for fusion to occur can be calculated by:

$$v^2 = \frac{1}{2\pi m_p \varepsilon_0} \frac{q_1 q_2}{r_p}$$  \hspace{1cm} (3.9)

where $v$ is the initial velocity of the incoming proton, and $r_p \simeq 10^{-15}$ m is the size of a proton. The root-mean-square thermal velocity of a proton is given by:

$$\frac{1}{2} m_p v_{\text{rms}}^2 = \frac{3}{2} k_B T$$  \hspace{1cm} (3.10)

where $k_B$ is the Boltzmann’s constant. Since it is assumed that one of the protons is at rest, the velocity that goes into Eq. 3.9 is the relative velocity of the two protons, so assuming that the protons collide head-on, we can assume that they only need half the velocity each for the collision to happen and the temperature for protons with rms velocity in a head on collision can interact and fuse then becomes:

$$T = \frac{1}{24\pi\varepsilon_0 k_B} \frac{q_1 q_2}{r_p}$$  \hspace{1cm} (3.11)

which for two protons is $3 \cdot 10^{10}$ K. The velocities of protons are not identical, so it could be that only the fastest moving protons would fuse, and that would be ok, but the temperature in the centre of the sun is only 15 MK, which would mean that the protons able to overcome the Coulomb barrier would have to move at roughly 100 times the rms velocity, which is a very small fraction of the total number of protons.
Exercise 3.15:
Assume that the protons are in thermal equilibrium so that they follow a Maxwellian distribution
\[
f_v(v) = \sqrt{\frac{2}{\pi}} \left(\frac{m_p}{k_B T}\right)^3 v^2 \exp\left[\frac{-m_p v^2}{2k_B T}\right]
\]
where \(f_v(v)\) is the probability that a proton has the velocity \(v\). The probability is normalised so that
\[
\int_{-\infty}^{\infty} f_v(v) dv = 1
\]
meaning that the is is certain that a proton has some velocity \(v\). Calculate how large a fraction of the protons have a velocity 10 times larger than the root-mean-square velocity
\[
v_{rms} = \sqrt{\frac{3k_B T}{m_p}}
\]
*Hint:* You should do a complicated integral here, but it turns out not to be necessary. Try to calculate the probability of finding a proton that has a velocity in the interval \(dv\) just around \(v_{rms}\) and compare it to what the probability is of finding a proton in the velocity interval \(dv\) around \(10v_{rms}\). Since \(v_{rms}\) is a typical velocity for the protons, what does this result mean?

Exercise 3.16:
Determine the fraction of hydrogen atoms in a gas of \(T = 10,000\) K having speeds between \(v_1 = 2 \cdot 10^4\) m s\(^{-1}\) and \(v_2 = 2.5 \cdot 10^4\) m s\(^{-1}\).
*Hint:* We already know that the integral over all velocities of the Exerc. 3.15 is one, so you now only need to do the integral over the Maxwell distribution between \(v_1\) and \(v_2\), and since they are almost the same, you can make the same assumption as in Exerc. 3.15.

It is obvious that some other process than just speed is needed to overcome the Coulomb barrier. The incoming particle uses the quantum tunneling effect to pass the Coulomb barrier. The tunneling effect relies among other things on the principle of non-locality, which means that there is a non-zero possibility of the particle actually being within the barrier at any
time. In general, Heisenbergs uncertainty principle shows that \( \Delta x \Delta p \gtrsim h \), so the location of the particles are never perfectly known, making it possible for a particle to ‘appear’ inside the Coulomb barrier. The smaller distance the particle has to tunnel, the larger the probability. When taking the tunneling into account, the reaction rate (the reactions per second) depends on the relative velocity between the reactants, and the cross section of the reactants. Cross sections should not be taken as a physical area, but more be thought of as a probability. The reaction rates pr unit mass can be expressed as:

\[
 r_{ik} = \frac{1}{\rho(1 + \delta_{ik})} \int \int v \sigma(v) dn_idn_k
\]

where \( \delta_{ik} \) is the Kronecker delta function, \( \rho \) is the mass density, \( v = |v_i - v_k| \) is the relative velocity of the two particles, \( dn_i \) and \( dn_k \) are the distributions of the particles in velocity space and \( \sigma(v) \) is the cross section of the reaction for relative velocity \( v \).

The \( \delta \)-function is needed because the two integrals are combining parti-

\footnote{Actually the uncertainty principle is \( \sigma_x \sigma_p \gtrsim \frac{1}{2} \hbar \) where \( \sigma_x \) and \( \sigma_p \) are the standard deviation of the distribution function of the position and momentum respectively and \( \hbar \) is the reduced Planck’s constant.}
3.4. ENERGY PRODUCTION RATE

cles of type \( i \) with velocity \( v_i \) and particle of type \( k \) with velocity \( v_k \). Now if \( i \neq k \) then the integrals make sure that the rate of particle type \( i \) and particle of type \( k \) fuse is calculated and summed. If the two particles types are the same, then we will be summing over the same distribution twice, and therefore the factor \( (1 + \delta_{ik}) \) appears in the denominator. To understand this better, think of the distribution of protons at a specific location in one dimensional space. Fig. 3.2 shows this case for a distribution with many protons (in black) and for a simple case with just two protons (in red). If we call the particle with velocity \(-25\) for particle one and the particle with velocity \(+11\) for particle two, then mathematically we take one value for \( i \) and integrate over \( j \) and sum that over all values of \( i \). In the case of the two protons, the factor \( n_i \) and \( n_j \) in the integrals make the reaction rate contribution zero unless \( i \) is \(-25\) or \( 11 \). When we do the integral we therefore get two contributions:

\[
\begin{align*}
  i &= -25 \quad \text{and} \quad j = 11 \\
  i &= 11 \quad \text{and} \quad j = -25
\end{align*}
\]

This leads to summing the reaction from two different collisions, but since there are only two different particles, only one collision can take place – a collision between particle one and two, so we have to half the total reaction rate when the particles in the reaction are the same.

In stellar interior, the distributions of the atoms are almost exactly Maxwellian (see Exerc. 3.1), so \( dn_i \) and \( dn_k \) are given. It is in general easier to calculate the reaction rates as a function of energy instead of relative velocity because for relative velocity one would have to integrate over both direction and speed for both particles.

Often the reaction rates (unit is kg\(^{-1}\) s\(^{-1}\)) is not given, but instead the function that allows the rate to be calculated. The proportionality function depends on energy or temperature, but is independent of the density of the particles involved in the fusion process. The proportionality function is often denoted by \( \lambda \) in the literature. It is connected to the rate per unit mass through:

\[
  r_{ik} = \frac{n_i n_k}{\rho (1 + \delta_{ik})} \lambda_{ik}
\]

The reaction rates (no longer pr unit mass!) can now be formulated as:

\[
  \lambda_{ik} = \sqrt{\frac{8}{m \pi (kT)^3}} \int_0^\infty \exp \left( -\frac{E}{kT} \right) E \sigma(E) dE \quad (3.13)
\]

where \( m = m_i m_k / (m_i + m_k) \) is the reduced mass and \( E = \frac{1}{2} m v^2 \) is the kinetic energy in the center of mass system. In the sun most reactions occur...
due to the tunneling effect, and for those reactions, the cross section is of the form:

\[
\sigma(E) = E^{-1} S(E) \exp \left( -\frac{m Z_i Z_k e^2 \pi}{2E c_0 h} \right) \quad (3.14)
\]

where \( S(E) \) is a slowly varying function of \( E \) (which can be assumed to be equal to one) and \( Z_i \) and \( Z_k \) is the number of protons in each core, while \( e \) is the elementary charge and \( h \) is Planck's constant.

**Exercise 3.17:**
What is the unit of \( \lambda \) in Eq. 3.13 (use your physical intuition)? What is the physical meaning?

**Exercise 3.18:**
For the proton-proton reaction, plot the two exponentials in Eq. 3.13 and their product in the same graph. Estimate the maximum and at what energy the maximum occurs.

The remaining integral is easy to evaluate if the reaction has a resonance - meaning that the reaction happens most efficiently just around a special energy, because then \( \sigma \) can be treated as a \( \delta \) function and simply set \( E = E_R \), and finally

\[
\lambda_{ik} \sim T^{-3/2} \exp (-E_R/kT) \quad (3.15)
\]

Resonant energies are generally of little importance for the Sun, even though some of the reactions for the CNO chain do have strong resonant energy contributions to their reaction rates. The cross section for reactions that do not show resonant energies can be found through experiments and quantum mechanical calculations to be equal to Eq. 3.14. We can now see that there are two exponential functions in the integral of Eq. 3.13. The first (already apparent in Eq. 3.13) comes from the Maxwellian distribution the energy of the particles, while the second (shown in Eq. 3.14) comes from the electrostatic barrier between the two particles with charges \( Z_i \) and \( Z_k \). The combination of the two exponentials creates a sharply peaked function - the Gamow peak\(^2\).

\(^2\)The Gamow peak is named after the Russian physicist Geor'yi Antonovich Gamov who considered the tunneling effect the first time in 1928, and was an early supporter of the Big Bang theory.
After approximating the Gamow peak by a Gaussian and assuming $S(E)$ to be a constant the reaction rates can be found to be

$$\lambda_{ik} = 4S(E_{\text{max}}) \left( \frac{2/3 \, m}{(k_B T)^{2/3}} \right)^{1/2} \frac{(b/2)^{1/3}}{(k_B T)^{1/3}} \exp \left( -\frac{3 (b/2)^{2/3}}{(k_B T)^{1/3}} \right)$$

where $S(E_{\text{max}})$ is the function $S$ evaluated at the energy at which the assumed Gamow peak has its maximum and

$$b = \sqrt{\frac{m}{2} \frac{e^2 \pi}{\varepsilon_0 \hbar}} \, Z_i Z_k$$

**Exercise 3.19:**
Find the maximum of the function in Eq. 3.16 and an expression for the value of the temperature where the maximum is achieved.

The reaction rates dependence on temperature is very general for non-resonant fusion reactions: A $T^{-2/3}$ multiplied with an exponential dependence on $T^{-1/3}$.

Table 3.1 gives a list of the equations for a number of reactions which are important in the Sun. The $\lambda$s are given in units of cm$^3$s$^{-1}$, so in order to get the reactions per second pr cubic centimeter, they must be multiplied by the two relevant number density $n$ of particles.
Exercise 3.20:
What factor must you multiply the $\lambda$s in Tbl. 3.1 with in order to convert them to SI units?

Exercise 3.21:
Calculate the maximum rate ($\lambda$) and at what temperature it is located for both the proton-proton and the $^{12}_6$C-proton fusion processes. Also calculate the full width of the Gaussian at $1/e$ of its maximum value for both of these processes.

Exercise 3.22:
Calculate the temperature of the different processes in the PP I branch for which the process is most effective. Which process needs the highest temperature?

Exercise 3.23:
Why do you think the expressions for the $\lambda$s in Tbl. 3.1 look so different from the expression in Eq. 3.16?

3.5 Evolution of element abundances

The rate of energy production from each of the production chains depends on which elements are available (for instance $^{12}_6$C for the CNO cycle and $^4_2$He for the PP II and PP III chains), and the rate of each of the different sub-steps in the cycle. The $\beta$-decay of the proton into a neutron in the first step of the PP chains is by far the slowest reaction in the PP chains, and controls the energy production of the sun.

The CNO cycle is not very important in the sun but is the main way energy production is done in heavier stars, where the temperature and pressure are higher at the center. In order for us to calculate the reaction rate for the electron capture of $^7$Be, we need to have the electron density. In the inner parts of the sun, we can safely assume that both hydrogen and helium are ionized. We will forget about the heavier elements, because they do not
3.5. EVOLUTION OF ELEMENT ABUNDANCES

supply that many electrons. The number densities can then be found by:

\[
np = \frac{\rho X}{\mu} \quad (3.18)
\]

\[
n_{He} = \frac{\rho Y}{4\mu} \quad (3.19)
\]

and the number of electrons coming from hydrogen and helium is one and two respectively, so the total number of electrons \( n_{e,tot} \) is the sum of the electrons from hydrogen \( n_{e,H} \) and from helium \( n_{e,He} \):

\[
n_{e,tot} = n_{e,H} + n_{e,He} = n_H + 2n_{He}
\]

\[
= \frac{\rho X}{\mu} + 2 \frac{\rho Y}{4\mu}
\]

\[
= \frac{\rho}{2m_u} \left[ X + \frac{1 - X}{2} \right]
\]

\[
= \frac{\rho}{2m_u} [2X + (1 - X)]
\]

\[
= \frac{\rho}{2m_u} (1 + X)
\]

When \( \lambda \) is the reaction rates (function of density of particles in the reaction), the reactions in the center of the sun can be written for all the elements that is used or produced in the three PP chains and the CNO cycle. As an example the evolution equation for \( ^1H \) looks like:

\[
\frac{\partial n_p}{\partial t} = -2\lambda_{pp}n_p^2 + \lambda_{pd}n_pn_{^2D} + 2\lambda_{33}n_{^2He}^2
\]

\[
-\lambda_{17}n_pn_{^3Li}^2
\]

\[
-\lambda_{17}n_pn_{^4Be}^2
\]

\[
-\lambda_{p12}n_pn_{^7C}^2 - \lambda_{p13}n_pn_{^8C}^2
\]

\[
-\lambda_{p14}n_pn_{^7N}^2 - \lambda_{p15}n_pn_{^8N}^2
\]

\[
(3.26)
\]

where the top line comes from the PP I chain, the second line comes from the PP II, the third line comes from the PP III chain while the fourth and fifth line come from the CNO chain.

**Exercise 3.24:**

Write up the evolution equation for \( ^1D, ^3He \) and \( ^4He \)
The evolution equations for the remaining species are:

\[
\begin{align*}
\frac{\partial n_{^7\text{Be}}}{\partial t} &= \lambda_{34} n_3 n_4 - \lambda_{e7} n_e n_{^7\text{Be}} - \lambda_{17} n_p n_{^7\text{Be}} \\
\frac{\partial n_{^7\text{Li}}}{\partial t} &= \lambda_{e7} n_e n_{^7\text{Be}} - \lambda_{8} n_{^8\text{Be}} \\
\frac{\partial n_{^7\text{B}}}{\partial t} &= \lambda_{17} n_p n_{^7\text{Be}} - \lambda_{8} n_{^8\text{B}} \\
\frac{\partial n_{^8\text{Be}}}{\partial t} &= \lambda_{8} n_{^8\text{B}} - \lambda'_{8} n_{^4\text{Be}} \\
\frac{\partial n_{^8\text{C}}}{\partial t} &= \lambda_{p15} n_p n_{^8\text{N}} - \lambda_{p12} n_p n_{^8\text{C}} \\
\frac{\partial n_{^8\text{N}}}{\partial t} &= \lambda_{p12} n_p n_{^8\text{C}} - \lambda_{13} n_{^8\text{N}} \\
\frac{\partial n_{^8\text{C}}}{\partial t} &= \lambda_{13} n_{^8\text{N}} - \lambda_{p13} n_p n_{^8\text{C}} \\
\frac{\partial n_{^8\text{N}}}{\partial t} &= \lambda_{p13} n_p n_{^8\text{C}} - \lambda_{p14} n_p n_{^8\text{N}} \\
\frac{\partial n_{^8\text{O}}}{\partial t} &= \lambda_{p14} n_p n_{^8\text{N}} - \lambda_{15} n_{^8\text{O}} \\
\frac{\partial n_{^7\text{N}}}{\partial t} &= \lambda_{15} n_{^8\text{O}} - \lambda_{p15} n_p n_{^7\text{N}}
\end{align*}
\]

The large number of evolution equations for the different species can be significantly simplified, since some of the reactions happen very fast, while others take a long time. We can therefore safely assume that the very fast reactions happen instantaneously. The very fast reactions are the β-decay of \(^8\text{B}\) (\(\lambda_8\)), \(^{13}\text{N}\) (\(\lambda_{13}\)) and \(^{15}\text{O}\) (\(\lambda_{15}\)) taking only a matter of seconds, and the split of \(^8\text{Be}\) into two α particles (\(\lambda'_8\)). Also the high probability of electron capture by \(^7\text{Be}\) compared to the production of \(^7\text{Be}\) and the destruction of \(^7\text{Li}\) makes the change in abundances of these two species tightly coupled. Finally deuterium comes into equilibrium very fast, so a number of safe
assumptions can be made. These are:

- \( \frac{\partial n_{1D}}{\partial t} = 0 \) (3.27)
- \( \frac{\partial n_{8B}}{\partial t} = 0 \) (3.28)
- \( \frac{\partial n_{4Be}}{\partial t} = 0 \) (3.29)
- \( \frac{\partial n_{7Li}}{\partial t} + \frac{\partial n_{4Be}}{\partial t} = 0 \) (3.30)

Since we know the densities of the ions that are part of the CNO cycle do not change we can therefore also assume that

- \( \frac{\partial n_{12C}}{\partial t} = \frac{\partial n_{13N}}{\partial t} = \frac{\partial n_{13C}}{\partial t} = \frac{\partial n_{14N}}{\partial t} = \frac{\partial n_{15O}}{\partial t} = \frac{\partial n_{15N}}{\partial t} = 0 \) (3.31)

That makes it possible to replace a lot of the equations, and we end up with

- \( \frac{\partial n_p}{\partial t} = -\frac{3}{2} \lambda_{pp} n_p^2 + \lambda_{33} n_3^2 - \lambda_{34} n_3 n_4 - 4 \lambda_{p14} n_p n_{14N} \) (3.32)
- \( \frac{\partial n_3}{\partial t} = \frac{1}{2} \lambda_{pp} n_p^2 - \lambda_{33} n_3^2 - \lambda_{34} n_3 n_4 \) (3.33)
- \( \frac{\partial n_4}{\partial t} = \frac{1}{2} \lambda_{33} n_3^2 + \lambda_{34} n_3 n_4 + \lambda_{p14} n_p n_{14N} \) (3.34)

By assuming that the mass of the sun does not change (that the mass of the reactants are the same and no mass is lost - even though it is), one can then assume that \( n_p = \rho X/m_p, n_3 = \rho Y_3/m_3 \) etc...... giving finally:

- \( \frac{\partial X}{\partial t} = m_u A_p (-3 r_{pp} + 2 r_{33} - r_{34} - 4 r_{p14}) \) (3.35)
- \( \frac{\partial Y_3}{\partial t} = m_u A_3 (r_{pp} - 2 r_{33} - r_{34}) \) (3.36)
- \( \frac{\partial Y_4}{\partial t} = m_u A_4 (r_{33} + r_{34} + r_{p14}) \) (3.37)

where the \( r \)'s are the reaction rates pr unit mass, and the full energy generation pr unit mass is then

- \( \varepsilon = \sum Q'_{ik} r_{ik} \) (3.38)

Table 3.1: The reaction rates in units cubic cm per second modified from Caughlan and Fowler, 1988. Temperature $T_9$ is in units of $10^9$ K. The electron capture by $^{7/2}\text{Be}$ has an upper limit at temperatures below $10^6$ K of $N_A \lambda_{c7} \leq 1.57 \times 10^{-7}/n_e$
Chapter 4

Equation of state

4.1 Introduction

The equation of state gives the connection between density, temperature and pressure or any variables derived from these. In general the equation of state is split into several terms. The simplest and the only relevant split is due to a number of different pressure forces that are present in stars.

4.2 Pressure forces

There are several possible forces that contribute to the pressure in stars. The most general is the gas pressure, radiative pressure and the pressure from degenerate electrons. For the sun only the gas and to a small degree the radiative pressure plays a role.

The radiative pressure comes about when the radiative flux is so large that the otherwise small momentum carried by the photons becomes significant. Stars where the radiative pressure is important for the structure are generally stars with very large fluxes, so the heaviest stars. The radiative pressure in the sun plays only a minor role in the central parts of the core, but is insignificant in the outer layers.

The pressure force from degenerate fermions is the main pressure force for two types of stars which are not stars in the traditional sense: White dwarfs and neutron stars. The force is a consequence of the Pauli principle which limits the number of fermions that can be forced into a given volume, because they cannot be in identical quantum states in the same location. When all the possible quantum states for the electrons in the compressed Carbon and Oxygen core of a white dwarf has been occupied it simply cannot
CHAPTER 4. EQUATION OF STATE

compress anymore. Except of course when the electrons are no longer there, which has happened for neutron stars, where the electrons has been forced into the cores of the atoms, and fused with protons to produce neutrons. The neutrons themselves now provides the pressure force for the neutron star in the same way that the electrons do for the white dwarf star. None of these degenerate pressures are important for the sun.

It is important to remember that pressure only provides a force, if there is a spatial gradient of the pressure. A location where the pressure is constant has no pressure force working on the gas.

4.2.1 Radiative pressure

The radiation pressure depends only on temperature and not on density:

\[ P_R = \frac{a}{3} T^4 \]  \hspace{1cm} (4.1)

where

\[ a = \frac{4\sigma}{c} \]  \hspace{1cm} (4.2)

**Exercise 4.1:**

What is the radiation pressure in the centre of the sun?

4.2.2 Gas pressure

The equation of state is rooted in atomic and molecular physics. That can easily be seen if we look at the simple equation of state for an ideal gas\(^1\)

\[ PV = Nk_B T \]  \hspace{1cm} (4.3)

where \( P \) is the pressure, \( V \) is a volume, \( N \) is the number of particles (atoms, molecules and electrons) in that volume, \( k_B \) is Boltzmanns constant and \( T \) is the temperature. As the number of particles \( N \) can be expressed as

\[ N = \frac{m}{\mu m_u} \]  \hspace{1cm} (4.4)

\(^1\)An ideal gas is a gas consisting of particles which collides completely elastically, i.e. they do not have internal structure that can absorb or contain energy (as in realistic atomic nuclei, or ions with electrons orbiting a atomic nucleus).
where $m$ is the mass inside the volume $V$, $\mu$ is the average atomic weight of the particles and $m_u$ is the atomic mass unit. The density can be expressed as

$$\rho = \frac{m}{V} \quad (4.5)$$

and by combining Eqs. 4.3 - 4.5

$$P = \frac{m}{\mu m_u} \frac{k_B T}{V} = \frac{\rho}{\mu m_u} k_B T \quad (4.6)$$

It is now easily seen that the pressure is intimately tied to the microphysics through the average weight of the particles, so in order to evaluate the pressure, the number and weight of each of the particles in the volume $V$ must be known. There are several examples of the electrons, not being the same temperature as the ions or that the distribution of velocities of the ions are such that one can not assign a single temperature to the ions. In these notes we will not investigate such complications, because as we have seen, the huge number of collisions between particles (see Exerc. 3.1) as well as the emissions and reabsorption of photons in the sun are able to smooth out any small scale temperature difference and is able to average the energy between the different particle species very quickly (see Chap. 5).

It is important to notice that the ideal gas is a gas where the particles making up the gas is much smaller than the average distance between them, and the particles can have no inner structure that can absorb or emit energy (such as molecules). That makes the ideal gas law applicable only for monoatomic gasses, at high temperature and low pressure.

**Exercise 4.2:**
What is the radial radiation pressure gradient, assuming the same temperature gradient as in Exerc. 3.1. What is the gas pressure gradient, assuming the same temperature gradient and that the density is constant? (Hint: assume $\mu = 0.6$ because all elements are assumed to be fully ionized.)

**Exercise 4.3:**
What is the relative importance of radiation pressure and gas pressure in the core of sun? (Hint: assume $\mu = 0.6$ because all elements are assumed to be fully ionized, $T = T_{core}$, $\alpha = 7.6 \cdot 10^{-16}$)
4.3 Abundances and molecular weight

Abundances of different elements are described usually by only three different parameters. They give the fractional abundances by weight for hydrogen \( X \), Helium \( Y \) and "metals" \( Z \). Sometimes more are added, for instance the abundance of \( ^3\text{He} \) \( Y_3 \) or carbon and nitrogen \( Z_{\text{CN}} \).

For a case with only neutral hydrogen and neutral helium,

\[
X = \frac{n_H m_H}{n_H m_H + n_{\text{He}} m_{\text{He}}} \quad (4.7)
\]
\[
Y = \frac{n_{\text{He}} m_{\text{He}}}{n_H m_H + n_{\text{He}} m_{\text{He}}} \quad (4.8)
\]
\[
Z = 0 \quad (4.9)
\]

and then the number of ions are

\[
\frac{X \rho}{1 m_u} \quad \text{Hydrogen ions} \quad (4.10)
\]
\[
\frac{Y \rho}{1 m_{\text{He}}} = \frac{Y \rho}{4 m_u} \quad \text{Helium ions} \quad (4.12)
\]
\[
0 \quad \text{Electrons from Helium} \quad (4.13)
\]

so the total number of particles are:

\[
n_{\text{tot}} = \frac{X \rho}{m_u} + \frac{Y \rho}{4 m_u} = \frac{\rho}{m_u} \left( X + \frac{Y}{4} \right) \quad (4.14)
\]

and now the mean molecular weight is just

\[
\mu_{\text{unit}} = \frac{\rho}{n_{\text{tot}}} \quad (4.15)
\]

This number has the unit mass, but it is always given as a dimensionless number. It is done by dividing by the unit nuclear mass so that the mean molecular mass becomes a unit-less number and in this case is

\[
\mu_0 = \frac{\rho}{m_u} = \frac{\rho m_u}{\rho (X + Y/4) m_u} = \frac{1}{X + Y/4} \quad (4.16)
\]

This is the typical definition of the mean molecular mass \textit{per particle}, but one could in principle want it \textit{per electron} instead and so it would be

\[
\mu_0 = \frac{\rho}{m_e} \quad (4.17)
\]
4.3. ABUNDANCES AND MOLECULAR WEIGHT

but this is not used very often, and if nothing is mentioned you can assume that it is per particle.

The mean molecular mass can be much more complicated for instance when electrons are involved or if many species of heavier elements are included. Assuming all Hydrogen and Helium is neutral and the heavier elements are fully ionized, then we may assumed that the heavier elements have released half as many electrons as their atomic mass (assuming the nucleus is half neutrons and half protons), then the number of atoms and electrons for a specific atomic species \( i \) is

\[
\begin{align*}
  n_{Z_i} &= \frac{Z_i \rho}{m_{Z_i}} = \frac{Z_i \rho}{A_i m_u} \\
  n_{e,Z_i} &= \frac{1}{2} A_i \frac{Z_i \rho}{A_i m_u}
\end{align*}
\]

(4.18)

(4.19)

where \( Z \) is the mass fraction of the metals, \( Z_i \) mass fraction of the metal we are looking at so that

\[
Z = \sum_i Z_i
\]

(4.20)

\( A_i \) is the total number of particles in the element nuclei (both protons and neutrons). The total number of particles is then

\[
\begin{align*}
  n_{\text{tot}} &= \sum_i n_{Z_i} + n_{e,Z_i} = \sum_i \frac{Z_i \rho}{A_i m_u} + \frac{1}{2} A_i \frac{Z_i \rho}{A_i m_u} \simeq \frac{Z \rho}{2 \mu_u}
\end{align*}
\]

(4.21)

where the last equality is based on \( A_i \) being rather large so the error we make by dropping the first term is small. The molecular average weight can now be written as

\[
\mu_0 = \frac{1}{X + Y/4 + Z/2}
\]

(4.22)

**Exercise 4.4:**
Write down an expression for the mean molecular weight for a gas where the hydrogen has a mass fraction \( X \) and is fully ionized, and the mass fraction of helium is \( Y \), where half of the helium is ionized once and the other half is ionized twice.
CHAPTER 4. EQUATION OF STATE

Exercise 4.5:
Write down an expression for the mean molecular weight of a gas with the hydrogen mass fraction $X$ with all of the hydrogen being ionized, the helium mass fraction is $Y$ with one third of the helium being neutral, one third ionized once and one third ionized twice. The gas also has a mass fraction $Z_C$ of carbon atoms, which are ionized twice, and a mass fraction $Z_N$ of nitrogen atoms which are ionized three times.

Exercise 4.6:
The mean molecular weight is usually defined per particle, but sometimes the mean molecular weight per electron is needed. Calculate the mean molecular weights per particle, per electron, and per nucleon for the sun. Assuming $X = 0.7346$, $Y = 0.2485$ and $Z = 0.017$ and fully ionized hydrogen, helium and metals. Also assume that the mean number of protons of metals is equal with 8, thus the mean number of protons and neutrons is 16. You will have to go through the derivation of the molecular mass in Sec. 4.3 to find the expression for each of these values, assuming that all atoms are ionized.

The mean molecular weight per particle can be calculated rather easily but one has to be careful. The formula is just the following

$$
\mu_0 = \frac{1}{\sum_{\text{particles provided pr nucleus} \times \text{mass fraction/nuclear particles}}}
$$

and it is completely general and can be used always for the mean molecular weight per particle.

Example 4.1:
As a simple example lets look at a gas of hydrogen which is not ionized and lets look at each of the elements in the terms in Eq. 4.23. Hydrogen provides no electrons, so the number of particles provided for each hydrogen atom is just one (the nucleus itself and no electrons), and the number of nuclear particles a hydrogen atom has is just one (a single proton). So now the mean molecular mass is just:

$$
\mu_0 = \frac{1}{1X/1} = \frac{1}{X}
$$

since there is only hydrogen, the mass fraction $X$ has to be one (remember the sum of the mass fractions needs to be one), so for this gas the
mean molecular mass \( \mu_0 = 1 \), which makes sense - all the particles are hydrogen atoms, and their mass is on average \( 1m_u \) - remember that \( \mu_0 \) is given in units of \( m_u \).

**Example 4.2:**
Let us now mix in some non ionized helium with a mass fraction of \( Y = 0.3 \), and so hydrogen needs to have a mass fraction \( X = 0.7 \). Helium also only provides one particle per nucleus (the nucleus itself and no electrons) but helium has 4 nuclear particles, so now

\[
\mu_0 = \frac{1}{\frac{1}{1}X + \frac{1}{4}Y} = 1.29
\]

which also makes sense. There are now not only the hydrogen that had a mean molecular weight of one, but now we have mixed in particles (helium) that are four times heavier, so the mean molecular mass per particle should go up.

**Example 4.3:**
Imagine a hydrogen gas (no other elements) but now half the hydrogen atoms are ionized. Now we need to split up the calculation in two parts because the two halves of the hydrogen gas are different. The mass fraction of hydrogen is again one since no other elements are present. The neutral part of the hydrogen atoms still provide only one particle per nucleus (the nucleus itself) and it has only one particle in its nucleus (a single proton). The other half of the hydrogen gas is ionized, so that part provides two particles per nucleus (the nucleus and one electron), and it still has only one particle in its nucleus (the single proton). So the mean molecular mass is now consisting of two hydrogen gasses with a mass fraction of \( \frac{1}{2} X \):

\[
\mu_0 = \frac{1}{\frac{1}{2}X + 2(\frac{1}{2}X)/1} = \frac{1}{\frac{3}{2}X} = \frac{2}{3}
\]

so now the mean molecular mass becomes \( \frac{2}{3} \) because \( X = 1 \). The reason is that the electrons weigh almost nothing compared to a hydrogen atom, but they do count as a particle, so the mean molecular mass per particle becomes less than one.
Example 4.4:
Finally let's look at a gas consisting of hydrogen \((X = 0.5)\), helium \((Y = 0.4)\) and other elements \((Z = 0.1)\). Half the hydrogen is ionized, one third of the helium is neutral, one third is ionized once and one third is ionized twice and the metals are also completely ionized (this is the standard approximation so the metals always enter the following way). We do the same as before, remembering all the different ionizations and particles:

\[
\mu_0 = \frac{1}{1(\frac{1}{2}X)/1 + 2(\frac{1}{2}X)/1 + 1(\frac{1}{3}Y)/4 + 2(\frac{1}{3}Y)/4 + 3(\frac{1}{3}Y)/4 + Z/2} = \frac{3}{2}X + \frac{1}{2}Y + \frac{1}{2}Z
\]

4.3.1 Corrections

There are two main corrections for the ionisation degree. Both of them are not very important for the Sun.

The electrostatic corrections take into account that the ionised particles also have an electric field around them, and therefore the collisions between particles are "softer" since they are surrounded by a "soft" electric field. The corrections are very small for the sun, on the order of a few percent.

The partially degenerate electron correction comes from the fact that deep in the Sun, the electrons are under such a large pressure, that they are affected by the Pauli principle that among other things says that if you force a large enough number of electrons into a very limited space, you cannot have electrons placed in the same location with the same momentum. There is therefore a correction to the electron pressure. For the Sun this only changes the electron pressure by a few percent at the very core of the Sun, but since the total pressure is set by the hydrostatic equilibrium, the pressure provided by the ions just changes to accommodate the change in the electron pressure.

There are a number of other corrections which can be included, but the effects of them are rather small, and they make computations of stellar models much more cumbersome. In general a table for the EOS is used instead, where one can lookup the values for the pressure \(P\), when the density and temperature is known.
4.3. ABUNDANCES AND MOLECULAR WEIGHT

The average weight of the particles, or mean molecular weight as it is also known can be calculated if one knows the temperature and density and one assumes that the gas is thermalized.
Chapter 5

Energy transport

5.1 Introduction

The large amount of energy produced in the center of stars are transported to the surface in two different ways. They are both effective, but the local temperature, pressure and chemical composition decides which of the two dominates.

The first transport mechanism is by the emission of photons, and the very small difference between the photons traveling outwards and inwards is large enough to carry the energy outwards.

The second energy transport mechanism is through motions, called convection. Convection happens, when the radiative transport of energy is not able to transport the energy fast enough, making the gas unstable, and setting it in motion. Hot gas wells up from the hot interior of the star, and when it reaches a location (the surface for the sun) where another transport mechanism is efficient enough to move the energy, it cools and flows back down into the star.

In principle heat conduction could also transport energy in stars, but it only has an effect in the cores of the most extreme stars with degenerate cores, mainly because the photon mean free path is very large because the electrons cannot absorb photons since any possible quantum states the electrons would have to jump to after the absorption of the photon are already filled with electrons, and the opposite is also true - no photons can be emitted from the core, since there are no free quantum states to fall into after the emission of the photon. We will not treat these extreme conditions in these notes.
5.2 Radiative transport

Radiative transport is the movement of energy by electromagnetic radiation. The gas inside a star is generally very opaque so the photons will travel a very short distance before being reabsorbed. The mean free path of a photon can be calculated by:

$$\lambda = \frac{1}{\kappa \rho}$$  \hspace{1cm} (5.1)

where $\kappa$ is the opacity (units of m$^2$ kg$^{-1}$), and $\rho$ is the mass density. The opacity in the sun is of the order one, and as the density in the sun is somewhere between one and 100,000 the mean free path is very small. The photons perform a random walk through the star. By assuming that the photons are reemitted instantly and that they are emitted in a random direction, they travel on average a certain distance $L$ by being reabsorbed $n$ times and on average traveling a distance $\lambda$ between absorptions. The distance $\lambda$ is also called the mean free path of the photons, and the three numbers are connected through:

$$L = \sqrt{n} \lambda$$  \hspace{1cm} (5.2)

If the photons had been emitted along the same direction as they were traveling before the were absorbed, the equation would just be $L = n \lambda$, but because they are emitted in any direction, they do not travel in a direct line, but needs to travel much further. The proof for the random walk equation can be easily done for one direction, with a certain step size $\lambda$. Imagine a photon that is emitted at location zero, after with it travels either a distance $-\lambda$ or a distance $+\lambda$ before being reabsorbed. It is reemitted and again travels a distance $-\lambda$ or $+\lambda$. The photons displacement $s_i$ after each step is then

$$s_i = \begin{cases} -\lambda & 50\% \text{ of the time} \\ +\lambda & 50\% \text{ of the time} \end{cases}$$  \hspace{1cm} (5.3)

then after $n$ steps the position $x$ of the photon is then

$$x(n) = \sum_{i=1}^{n} s_i$$  \hspace{1cm} (5.4)

and the displacement squared is then

$$x^2(n) = \left( \sum_{i=1}^{n} s_i \right)^2$$  \hspace{1cm} (5.5)
CHAPTER 5. ENERGY TRANSPORT

The average position of the photon will always be at $x = 0$, but it only means that the possibility of finding the photon somewhere is a distribution centered at $x = 0$, not that the photon is stuck at $x = 0$ for all time, the probability of finding the photon at a certain distance from $x = 0$ increases with the number of times it has been reemitted. To figure out how large the broadening of the probability is we can rewrite the square displacement:

$$x^2(n) = \left( \sum_{i=1}^{n} s_i \right)^2 = \sum_{i=1}^{n} s_i \sum_{j=1}^{n} s_j = \sum_{i=1}^{n} s_i^2 + \sum_{i=1}^{n} \sum_{j=i+1}^{n} s_i s_j$$

(5.6)

now consider the second sum. There are four possibilities at each step, each being equally probable. $s_i$ and $s_j$ can both be positive or both be negative, in both cases making the product positive. If either of them are negative while the other is not, the product will be negative, so:

$$s_i s_j = \begin{cases} +\lambda^2 & 50\% \text{ of the time} \\ -\lambda^2 & 50\% \text{ of the time} \end{cases}$$

(5.7)

so on average the second sum will be zero. But at the same time $s_i^2 = \lambda^2$ independently of whether $\lambda$ is positive or negative. So the average after $n$ steps must be

$$<x^2(n)> = \lambda^2 n$$

(5.8)

which is identical to Eq. 5.2.

5.2.1 Photon diffusion

As we have just seen the photon mean free path is very small in the sun. The transport of energy can therefore also be seen as a diffusion of photons from a more photon dense volume (the core of the sun) to a less photon dense volume (the outer regions of the sun). The diffusion equation in a 3 dimensional space in general from can easily be written as:

$$j = -D \nabla n$$

(5.9)

where $n$ is density of the medium being diffused, $j$ is the flux created by the diffusion and $D$ is a diffusion constant. The diffusion constant is given as

$$D = \frac{1}{3} v \lambda$$

(5.10)
where $v$ is the velocity of the particles. In this case the density of photons is given by the radiative energy density:

$$U = aT^4$$  \hspace{1cm} (5.11)

where $a$ is the radiation density constant, and so the photon energy flux is:

$$F_R = -\frac{4}{3}a\kappa\lambda T^3 \partial T \frac{\partial T}{\partial r} = -\frac{4}{3}\kappa\rho \frac{\partial T}{\partial r} = -\frac{16}{3}\sigma T^3 \frac{\partial T}{\partial r}$$  \hspace{1cm} (5.12)

where we have used that $a = \frac{4\sigma}{c}$ where $\sigma$ is Stefan Boltzmann’s constant.

We also know that the radiative flux has to carry all the energy produced by the star, so we also know that

$$F_R = \frac{L}{4\pi r^2}$$  \hspace{1cm} (5.13)

so we can solve for the temperature gradient

$$\frac{L}{4\pi r^2} = -\frac{16}{3}\sigma T^3 \frac{\partial T}{\partial r}$$

$$\frac{\partial T}{\partial r} = -\frac{3\kappa\rho L}{64\pi r^4 \sigma T^3} \frac{1}{4\pi r^2 \rho}$$

$$\frac{\partial T}{\partial m} = -\frac{3\kappa L}{256\pi r^4 \sigma T^3}$$  \hspace{1cm} (5.14)

In principle Eq. 5.14 is only true when all the energy is transported by radiation. The gradient in temperature is the gradient needed for the photons to be able to move all the energy out through the sun, so if some other mechanism would set in that was more efficient than energy transport by radiation, the temperature gradient from Eq. 5.14 would not be correct.

### 5.3 Convective transport

Convective transport is the transport of energy by motions. It depends on the stability of the gas for small perturbations. Convection in stars is similar to what happens when you heat water in a pot on a stove. The stove heats the pot and the water at the bottom of the pot. Water is convectively unstable under normal circumstances, and the effect on the water is most obvious just before it boils. Large cells of water well up from below where it has been heated, when it reaches the surface, it cools when coming in contact with the colder air, and then flows back down to the bottom of the
CHAPTER 5. ENERGY TRANSPORT

pot, usually along the cool sides of the pot. In stars the same effect happens, and in the sun, the effect is almost identical. The gas is being heated from below, and the gas becomes convectively unstable, and the same large cells of upwelling gas can be seen on the solar surface, but since there are no “sides” on the sun, the cells are surrounded by cooler downflow lanes as can be seen in 5.1.

To find out if the gas in a medium is convectively unstable, meaning that it will start to move even at the smallest perturbation, a number of thermodynamic principles must be understood. Thermodynamics is a very large subject, and only the absolute minimum needed to understand convective transport will be included in these notes.

Figure 5.1: The convective pattern on the solar surface, showing the bubbles of hot gas sticking up above the cool and dark downflow valleys. The observation is made with the Swedish 1-m Solar Telescope on the Canary Islands. Tick marks are arcseconds corresponding to roughly 725 km on the solar surface. The suns surface is seen under an angle of 51°.

5.3.1 Thermodynamics

The behavior of a gas can be explained with the help of a number of constants and principle laws. The first relation is the equation for added heat per unit mass:

\[ dq = du + P \, dV \]  
(5.15)
5.3. CONVECTIVE TRANSPORT

and the internal energy $u$ and the specific volume $V = 1/\rho$. It is important to notice that $du$ is a total differential form, so that for instance:

$$
du = \left( \frac{\partial u}{\partial V} \right)_T dV + \left( \frac{\partial u}{\partial T} \right)_V dT \quad (5.16)
$$

These expressions are rather useless for our purposes so we need to reform them into something more useful. We want to get an expression for what happens to the gas if we add just a small amount of energy $dq$, and that involves both that we know something about the gas itself and how it changes its properties when it is being perturbed by outside disturbances. In order to understand these details we need to be as general as possible. To that end we assume a very general equation of state $\rho(P,T)$ and $u(\rho,T)$, which usually is also dependent on the chemical composition, but we assume here the chemical composition is constant or at least that the evolution of the chemical composition is so slow that it has no consequence. Be aware that the independent variables ($P$ and $T$ for $\rho(P,T)$ and $\rho$ and $T$ for $u(\rho,T)$ is chosen specifically but could have been chosen differently – as long as two of the three $P$, $T$ and $\rho$ are kept as primary variables and the last as a derived quantity. In the following we will use the independent variables mentioned above. A number of derivatives will be needed later on and to simplify things they will be renamed by the following symbols:

$$
\alpha = \left( \frac{\partial \ln \rho}{\partial \ln P} \right)_T = \frac{P}{V} \left( \frac{\partial V}{\partial P} \right)_T \quad (5.17)
$$

$$
\delta = - \left( \frac{\partial \ln \rho}{\partial \ln T} \right)_P = \frac{T}{V} \left( \frac{\partial V}{\partial T} \right)_P \quad (5.18)
$$

The subscripts $T$, $P$ and later $V$ means that the derivatives are to be taken at constant temperature, pressure and specific volume respectively. We can now write the equation of state as

$$
\frac{d\rho}{\rho} = \alpha \frac{dP}{P} - \delta \frac{dT}{T} \quad (5.19)
$$

**Exercise 5.1:**

Show Eq. 5.19 using Equations 5.15–5.18, alternatively show Eq. 5.19 using Eq. 5.17 and Eq. 5.18 repeating what is done in Eq. 5.16.

We also need the specific heats of which there are two. Specific heats are the amount of energy needed to raise the temperature of a unit mass of the
CHAPTER 5. ENERGY TRANSPORT

gas by one Kelvin, at constant pressure (Eq. 5.20) and at constant specific volume (Eq. 5.21):

\[ c_P = \left( \frac{dq}{dT} \right)_P = \left( \frac{\partial u}{\partial T} \right)_P + P \left( \frac{\partial V}{\partial T} \right)_P \]  
(Eq. 5.20)

and

\[ c_V = \left( \frac{dq}{dT} \right)_V = \left( \frac{\partial u}{\partial T} \right)_V \]  
(Eq. 5.21)

Eq. 5.15 can now be written

\[ dq = \left( \frac{\partial u}{\partial V} \right)_T dV + \left( \frac{\partial u}{\partial T} \right)_V dT + P dV \]  
\[ = c_V dT + \left[ \left( \frac{\partial u}{\partial V} \right)_T + P \right] dV \]  
(Eq. 5.22)

If we choose a case where the pressure is kept constant, then we can find a change in temperature that only changes the volume and we can then use the derivative of the volume with temperature to get

\[ dq = c_V dT + \left[ \left( \frac{\partial u}{\partial V} \right)_T + P \right] \left( \frac{\partial V}{\partial T} \right)_P dT \]  
(Eq. 5.23)

At the same time a change in energy \( dq \) at constant pressure due to a change in temperature is the definition of heat capacity, so in this case

\[ dq = c_P dT \]  
(Eq. 5.24)

so we finally get

\[ c_P dT = c_V dT + \left[ \left( \frac{\partial u}{\partial V} \right)_T + P \right] \left( \frac{\partial V}{\partial T} \right)_P dT \]  
\[ (c_P - c_V) dT = \left[ \left( \frac{\partial u}{\partial V} \right)_T + P \right] \left( \frac{\partial V}{\partial T} \right)_P dT \]  
\[ c_P - c_V = \left[ \left( \frac{\partial u}{\partial V} \right)_T + P \right] \left( \frac{\partial V}{\partial T} \right)_P \]  
(Eq. 5.25)

Even if we have an equation of state, \( u \) is still not a very useful variable to use, so in order to get rid of the derivative of \( u \) we can use the equation for the entropy

\[ ds = \frac{dq}{T} = \frac{1}{T} (du + P dV) \]  
(Eq. 5.26)
5.3. CONVECTIVE TRANSPORT

and if we insert the full derivative for \( u \) in Eq. 5.26, we can find

\[
\frac{ds}{dT} = \frac{1}{T} du + \frac{1}{T} P dV
\]

\[
= \frac{1}{T} \left[ \frac{\partial u}{\partial T} \right] V dT + \left( \frac{\partial u}{\partial V} \right)_T dV + \frac{1}{T} P dV
\]

\[
= \frac{1}{T} \left( \frac{\partial u}{\partial T} \right)_V dT + \frac{1}{T} \left[ \left( \frac{\partial u}{\partial V} \right)_T + P \right] dV
\]

(5.27)

We compare that with the expression for the full derivative of \( s \)

\[
\frac{ds}{dT} = \left( \frac{\partial s}{\partial T} \right)_V dT + \left( \frac{\partial s}{\partial V} \right)_T dV
\]

(5.28)

and then we can see that

\[
\left( \frac{\partial s}{\partial T} \right)_V = \frac{1}{T} \left( \frac{\partial u}{\partial T} \right)_V \text{ and } \left( \frac{\partial s}{\partial V} \right)_T = \frac{1}{T} \left[ \left( \frac{\partial u}{\partial V} \right)_T + P \right]
\]

(5.29)

Since

\[
\frac{\partial}{\partial V} \left[ \frac{\partial s}{\partial T} \right] = \frac{\partial}{\partial T} \left[ \frac{\partial s}{\partial V} \right]
\]

(5.30)

we can take the derivative with respect to \( V \) of the left expression in Eq. 5.29 then that should be the same as the derivative with respect to \( T \) of the right expression, so we get

\[
\frac{\partial}{\partial V} \left[ \frac{1}{T} \left( \frac{\partial u}{\partial T} \right)_V \right] = \frac{\partial}{\partial T} \left[ \frac{1}{T} \left( \left( \frac{\partial u}{\partial V} \right)_T + P \right) \right]
\]

\[
\frac{1}{T} \frac{\partial^2 u}{\partial T \partial V} = -\frac{1}{T^2} \left( \frac{\partial u}{\partial V} \right)_T + \frac{1}{T} \left( \frac{\partial^2 u}{\partial T \partial V} \right) - \frac{1}{T^2} P + \frac{1}{T} \left( \frac{\partial P}{\partial T} \right)_V
\]

\[
0 = -\left( \frac{\partial u}{\partial V} \right)_T - P + T \left( \frac{\partial P}{\partial T} \right)_V
\]

(5.31)

We now have an expression for the derivative of \( u \) we needed in Eq. 5.25, and by inserting we get

\[
c_P - c_V = \left( \frac{\partial V}{\partial T} \right)_P \left( \frac{\partial P}{\partial T} \right)_V T
\]

(5.32)

and since we can transform the second term

\[
\left( \frac{\partial P}{\partial T} \right)_V = -\left( \frac{\partial V}{\partial P} \right)_T P \frac{\delta}{T\alpha}
\]

(5.33)
we finally arrive at

\[ c_P - c_V = T \left( \frac{\partial V}{\partial T} \right)_p \frac{P \delta}{T \alpha} = \frac{P \delta^2}{\rho T \alpha} \]  

(5.34)

which for an ideal gas transforms into

\[ c_P - c_V = nk_B \]  

(5.35)

where \( k_B \) is Boltzmann's constant and \( n \) is the number density of atoms or molecules.

**Exercise 5.2:**
Using the first law of thermodynamics (Eq. 5.15) and assuming a process where the volume does not change, so that

\[ dq = c_V dT = du \]

find an expression for the \( c_V \) for an ideal gas.

**Exercise 5.3:**
Deduce the expression for \( c_P - c_V \) (Eq. 5.35) by using the ideal equation of state and Eq. 5.34.

**Exercise 5.4:**
Using the answers to Exerc. 5.2 and Exerc. 5.3, deduce an expression for \( c_P \)

Eq. 5.15 can now be transformed

\[ dq = du + PdV \]

\[ = \left[ \left( \frac{\partial u}{\partial V} \right)_T dV + \left( \frac{\partial u}{\partial T} \right)_V dT \right] + PdV \]

\[ = \left( \frac{\partial u}{\partial V} \right)_T dV + c_V dT + PdV \]

\[ = c_V dT + \left[ \left( \frac{\partial u}{\partial V} \right)_T + P \right] dV \]  

(5.36)
using Eq. 5.31 and Eq. 5.33 we get
\[ dq = c_v dT + T \left( \frac{\partial P}{\partial V} \right) dV \]
\[ = c_v dT + \left[ \frac{T P \delta}{T \alpha} \right] dV \]
\[ = c_v dT + \frac{P \delta}{\alpha} dV \]  
(5.37)

we know need to convert \( dV \) and that can be done using Eq. 5.19 for the general equation of state:
\[ \frac{d \rho}{\rho} = \frac{\alpha dP}{P} - \frac{\delta dT}{T} \]
\[ V \left( - \frac{1}{V^2} \right) dV = \alpha \frac{dP}{P} - \delta \frac{dT}{T} \]
\[ dV = -\alpha V \frac{dP}{P} + V \delta \frac{dT}{T} \]  
(5.38)

inserting that expression back into Eq. 5.37 gives
\[ dq = c_v dT + \frac{P \delta}{\alpha} \left( -\frac{\alpha V}{P} dP + \frac{V \delta}{T} dT \right) \]
\[ = c_v dT - \delta V dP + \frac{P \delta^2}{\alpha T} dT \]
\[ = \left( c_v + \frac{P \delta^2}{\alpha T} \right) dT - \delta \frac{dP}{\rho} \]  
(5.39)

and finally using Eq. 5.34
\[ dq = \left( c_v + \frac{P \delta^2}{\rho T \alpha} \right) dT - \delta \frac{dP}{\rho} \]
\[ = c_p dT - \delta \frac{dP}{\rho} \]  
(5.40)

We are now almost done. In our case we are interested in how the temperature, density and pressure would have to change inside the star in order for it to be stable to small perturbations. If a small perturbation moves a parcel of gas up or down, we need to know how its pressure, temperature and density changes. If the changes are such that it now gets the same temperature, density and pressure as its new surroundings, the star would be very stable, and nothing much would move. That same would be true if
the parcel would start to move back towards its initial position after being moved up or down. We will look at how the temperature structure looks for a star where the gas can be perturbed up or down without becoming unstable. In such a case the temperature, density and pressure is exactly the same as the surroundings after it has moved, so there is no exchange of energy from the parcel to the surroundings. Such a process is adiabatic, and so we can use the definition of the adiabatic temperature gradient to be:

$$\nabla_{ad} = \left( \frac{\partial \ln T}{\partial \ln P} \right)_s$$  \hspace{1cm} (5.41)

and using Eq. 5.40 and the assumption that there is no exchange of energy between the package of gas we are looking at and its surroundings we now have

$$T \, ds = 0 = dq = c_P \, dT - \frac{\delta}{\rho} \, dP$$ \hspace{1cm} (5.42)

or

$$\left( \frac{dT}{dP} \right)_s = \frac{\delta}{\rho c_P}$$ \hspace{1cm} (5.43)

so that the adiabatic temperature gradient can now be rewritten as

$$\nabla_{ad} = \left( \frac{P}{T} \frac{dT}{dP} \right)_s = \frac{P \delta}{T \rho c_P}$$ \hspace{1cm} (5.44)

**Exercise 5.5:**
Show that using the equation of state for an ideal gas (Eq. 4.3), Eq. 5.34 can be simplified to Eq. 5.35

**Exercise 5.6:**
By inserting the expression for the pressure of an ideal gas into Eq. 5.44 and find a value for $\nabla_{ad}$ for an ideal gas

### 5.3.2 Convective instability

Convection can easily be explained as a stratified gas or a fluid that unstable to small changes in position. Imagine a small parcel or volume of gas is displaced slightly up towards the stellar surface. Assume that the movement is fast enough for the parcel not to exchange heat with its surroundings, while at the same time having time to get into pressure equilibrium. These assumptions might not seem very realistic, so we will see if they are realistic.
or not later in this chapter. In certain circumstances the small parcel of
gas becomes buoyant (the density is lower than its surroundings) as an
effect of that movement. If those circumstances are present, then the gas is
convectively unstable, as the gas will continue to rise through the star until
the circumstances change.

The assumptions we have made in this example are that the timescale
for a pressure perturbation to travel across the volume of the gas parcel,
is smaller than the timescale for a photon to cross the parcel taking into
account the times it is absorbed and reemitted. That makes it obvious that
we are talking about a parcel of gas that is many times larger than the
mean free path of a photon, otherwise the photons would make the parcel
the same temperature as the gas surrounding it in a time that is on the order
of the photon flight time from one side of the parcel to the other. A pressure
perturbation travels with sound speed. The sound speed for an ideal gas is

\[ c_s^2 = \gamma \frac{P}{\rho} \quad (5.45) \]

so a pressure perturbation will travel across its radius \( \delta r \) in a time \( \delta t \)

\[ \delta t_s = \sqrt{\frac{\rho}{\gamma P}} \delta r \quad (5.46) \]

A photon will have a mean free path through the volume of

\[ \lambda = \frac{1}{\rho \kappa} \quad (5.47) \]

and the number of steps it will have to take is (see Sec. 5.2)

\[ N = \frac{\delta r^2}{\lambda^2} \quad (5.48) \]

and finally the time it would take would be

\[ \delta t_r = \frac{N \lambda}{c} + N \delta t_{em} \quad (5.49) \]

where \( c \) is the speed of light, and \( \delta t_{em} \) is the time it on average takes be-
 tween an absorption and before the photon is reemitted. In order for our
assumption to be correct

\[
\begin{align*}
\delta t_s & < \delta t_r \\
\frac{\delta r}{c_s} & < \frac{N \lambda}{c} + N \delta t_{em} \\
\frac{\delta r}{c_s} & < N \left( \frac{\lambda}{c} + \delta t_{em} \right) \\
\frac{\delta r}{\lambda} & < \frac{\delta r^2}{\lambda^2} \frac{c}{c_s} \left( \frac{\lambda}{c} + \delta t_{em} \right) \\
1 & < \frac{\delta r}{\lambda^2} \frac{c}{c_s} \left( \frac{\lambda}{c} + \delta t_{em} \right) \\
\frac{\delta r}{\lambda} & > \frac{\lambda^2}{c_s} \left( \frac{c}{\lambda + c \delta t_{em}} \right) \\
\frac{\delta r}{\lambda} & > \frac{c}{c_s} \left( \frac{\lambda}{\lambda + c \delta t_{em}} \right)
\end{align*}
\] (5.50)

Here we can see that the \( \delta r \) in units of the mean free path of the photons needs to be roughly \( c/c_s \) which is clearly large. The expression in the parentheses on the right hand side can then decrease the requirement for \( \delta r \) if the distance a photon can travel during the time it is absorbed by an atom is on the order of or larger than the mean free path \( \lambda \). It is hard to estimate if this is realistic. It turns out that inside stars, the sound speed is very high so it makes this requirement less stringent.

**Exercise 5.7:**
Calculate the requirement for \( \delta r \) at the solar core, the bottom of the convection zone and in the photosphere, using an ideal equation of state, so that the sound speed can be expressed as \( c_s^2 = \gamma P/\rho \) where \( \gamma = 5/3 \). Use the values found in the appendices and assume that the opacity \( \kappa = 1 \text{ m}^2 \text{ kg}^{-1} \).

5.3.3 Onset of convection

Imagine now a parcel of gas that starts out at a certain height \( r \), where it has a density \( \rho_0 \), pressure \( P_0 \) and temperature \( T_0 \). The gas of the star around the parcel has a density \( \rho_0^* \), pressure \( P_0^* \) and temperature \( T_0^* \) which are equal to inside the parcel, i.e.

\[
\rho_0 = \rho_0^* \quad , \quad P_0 = P_0^* \quad \text{and} \quad T_0 = T_0^*
\] (5.51)

The parcel is now displaced upward in the stably stratified stellar interior by
a distance $\delta r$ from a position $r$ to $r+\delta r$. During the adiabatic displacement, the density $\rho_0$ of the parcel changes to $\rho$ while the density outside changes to $\rho^*$. The pressure inside the parcel $P$ adjusts to the same level as the pressure outside the parcel $P^*$. If the density of parcel after the displacement is lower than the surroundings, the parcel is buoyant and will move. So in order for the stratification to be convectively unstable, the density contrast can be written as

$$0 > \rho - \rho^* = \delta r \left[ \frac{\rho - \rho_0}{\delta r} - \frac{\rho^* - \rho}{\delta r} \right] = \delta r \left[ \left( \frac{\partial \rho}{\partial r} \right)_{\text{ad}} - \frac{\partial \rho}{\partial r} \right]$$

(5.52)

where the adiabatic gradient is part of the assumption of the parcel displacement being adiabatic. If we assume an ideal gas where the mean molecular weight $\mu$ can vary then

$$\left[ \frac{\partial P}{\partial r} \right] = \frac{m_u}{k_B} \left[ \frac{\partial P}{\partial r} \right] = \frac{m_u}{k_B} \left[ \frac{\mu \partial P}{T \partial r} + \frac{P \partial \mu}{T \partial r} + \frac{P \mu}{T \partial r} \right]$$

(5.53)
and then inserting into Eq. 5.52 gives

\[ 0 > \delta r \left[ \frac{m_u}{k_B} \left( \frac{\mu}{T} \frac{\partial P}{\partial r} + \frac{P}{T} \frac{\partial \mu}{\partial r} + P \mu \frac{\partial T^{-1}}{\partial r} \right) \right]_{\text{ad}} - \left( \frac{\mu}{T} \frac{\partial P}{\partial r} + \frac{P}{T} \frac{\partial \mu}{\partial r} + P \mu \frac{\partial T^{-1}}{\partial r} \right) \]

Using that the pressure at the new height \( r + \delta r \) inside and outside the parcel is the same so that the gradient in pressure inside and outside the parcel is also the same,

\[ 0 > \left( \frac{\partial P}{\partial r} + P \mu T \frac{\partial T}{\partial r} - P \mu \frac{\partial T}{\partial r} \right)_{\text{ad}} - \left( \frac{\partial P}{\partial r} + P \mu T \frac{\partial T}{\partial r} - P \mu \frac{\partial T}{\partial r} \right) \]

so finally we get

\[ 0 > \left[ P \frac{\partial \mu}{\partial r} - P \mu T \frac{\partial T}{\partial r} \right]_{\text{ad}} - P \frac{\partial \mu}{\partial r} + P \mu T \frac{\partial T}{\partial r} \]  

(5.55)

The instability criterion says that if the temperature gradient is lower than the adiabatic temperature gradient, then we have a convective instability, and the gas will begin to move. There are two terms on the right, that can influence this criterion. If we assume that the mean molecular weight does not change under adiabatic expansion or contraction \( (\partial \mu / \partial r)_{\text{ad}} = 0 \) and we are dealing with the sun, then the mean molecular weight decreases with radius\(^1\), so that the term \( (\partial \mu / \partial r) \) is stabilizing – the temperature gradient

\[ -\mu \frac{\partial T}{\partial r} > -\mu \left( \frac{\partial T}{\partial r} \right)_{\text{ad}} + T \left( \frac{\partial \mu}{\partial r} \right)_{\text{ad}} - T \frac{\partial \mu}{\partial r} \]  

(5.56)

\[ \frac{\partial T}{\partial r} < \left( \frac{\partial T}{\partial r} \right)_{\text{ad}} - T \left( \frac{\partial \mu}{\partial r} \right)_{\text{ad}} + \frac{T}{\mu} \frac{\partial \mu}{\partial r} \]  

(5.57)

\(^1\)For a gas consisting of only hydrogen and helium, both fully ionized, the mean molecular weight \( \mu = 1/(2X + 3/4Y) \) which for the sun decreases with radius because at the center of the sun, the mass fraction of Helium is much larger than at the surface. There are though regions in the outer parts of the sun where He goes from being twice ionized to only ionized once, which means that at that radius the mean molecular weight actually increases.
5.3. CONVECTIVE TRANSPORT

can now be larger than the adiabatic temperature gradient. The instability criterion is often recast into

$$\nabla > \nabla_{\text{ad}}$$  \hspace{1cm} (5.58)

where $\nabla_{\text{ad}}$ is defined by Eq. 5.41 and $\nabla$ is then the same double logarithmic gradient, but for the stellar stratification being investigated. It is equivalent to Eq. 5.57 except for the terms depending on the mean molecular weight, since

$$\frac{\partial \ln T}{\partial \ln P} > \frac{\partial \ln T}{\partial \ln P}_{\text{ad}}$$  \hspace{1cm} (5.59)

$$\frac{\partial T}{\partial r} < \left(\frac{\partial T}{\partial r}\right)_{\text{ad}}$$  \hspace{1cm} (5.60)

because the parcel is supposed to be rising adiabatically and have the same pressure as outside, so the two gradients are identical.

**Exercise 5.8:** Why does the inequality sign change from Eq. 5.59 to Eq. 5.60?

5.3.4 Convective energy flux

In general the energy flux at any point in a star, outside its energy producing core, has to obey

$$F_R + F_C = \frac{L}{4\pi r^2}$$  \hspace{1cm} (5.61)

where the $F_R$ is the radiative flux found in Eq. 5.12, $F_C$ is the convective flux and $L$ is the luminosity of the star. We have here implicitly assumed that heat conduction is not important. The convective flux can from first principles be written as

$$F_C = \rho c_P v \Delta T$$  \hspace{1cm} (5.62)

which just states that the convective flux, is the excess energy $\rho c_P \Delta T$ a parcel of density $\rho$ can move, with the velocity $v$. The trouble is of course to estimate what the velocity and temperature difference is. In the following we will try to estimate what the temperature difference between the parcel and the surroundings ($\Delta T$) is and what the convective velocity ($v$) is.
CHAPTER 5. ENERGY TRANSPORT

The temperature difference

We imagine as in Sec. 5.3.3 that we have a rising parcel of gas, which is continuously in pressure equilibrium with its surroundings, but here we cannot assume that it rises adiabatically, because the time it takes for the parcel to rise might be long, and so it would be able to exchange energy with its surroundings.

To estimate the temperature difference, we write

\[ \Delta T = \left( \left( \frac{\partial T}{\partial r} \right)_p - \left( \frac{\partial T}{\partial r} \right)^\star \right) \delta r = \left( \nabla^\star - \nabla_p \right) \frac{T \delta r}{H_p} \quad (5.63) \]

where a subscript \( p \) is for the parcel, while a superscript \( \star \) is for the star. We have used the definition of the pressure scale height.

\[ H_p = -P \frac{\partial r}{\partial P} \quad (5.64) \]

to change the gradient of \( r \) to a gradient in pressure:

\[ \nabla = \frac{\partial \ln T}{\partial \ln P} = P \frac{\partial r}{\partial P} \frac{\partial \ln T}{\partial r} = -H_p \frac{\partial \ln T}{\partial r} = -\frac{H_p}{T} \frac{\partial T}{\partial r} \quad (5.65) \]

Exercise 5.9:

Assume that we are looking at a static atmosphere where gravity, and pressure are the only two forces present. Assume also that gravity can be represented by the gravitational acceleration and is constant and has the value \( g \). Assume furthermore that gravity is aligned along \(-r\).

Write down the force balance, and use it to find an equation for \( P \) as a function of \( r \). What is the pressure scale height, for an ideal gas, when the pressure scale height is defined as the height over which the pressure drops by a factor \( 1/e \)?

We need to assume a value for the distance travelled \( \delta r \) by a parcel of gas in order to get further with Eq. 5.62. For historical reasons the distance usually assumed is half a mixing length

\[ \delta r = \frac{1}{2} l_m \quad (5.66) \]
5.3. CONVECTIVE TRANSPORT

Inserting this directly into Eq. 5.62 we get:

\[ F_C = \rho c_p v \frac{T_{l_m}}{2 H_p} (\nabla^* - \nabla_p) \]  

(5.67)

If we split this into two terms by introducing \( \nabla_{ad} \) which is the temperature gradient for an adiabatically rising parcel we get:

\[ F_C = \rho c_p v \frac{T_{l_m}}{2 H_p} (\nabla^* - \nabla_{ad}) + \rho c_p v \frac{T_{l_m}}{2 H_p} (\nabla_{ad} - \nabla_p) \]  

(5.68)

These two terms can be understood quite easily. The first term is just the convective flux we would have if the parcels were rising adiabatically. The second term is the modification needed when taking into account the radiative losses of the rising parcel. The second term is just the radiative loss of the parcel so by using the radiative flux (Eq. 5.12) and assuming that the gradient in temperature from the outside to inside of the parcel is just twice the temperature difference divided by the diameter \( d \) of the parcel:

\[ f_R = -\frac{16}{3} \frac{\sigma T^4}{\kappa \rho} \frac{2\Delta T}{d} = -\frac{16}{3} \frac{\sigma T^4}{\kappa \rho H_p} \frac{l_m}{d} (\nabla^* - \nabla_p) \]  

(5.69)

The flux is the radiative losses per unit area so we need to multiply it with the surface of the parcel \( S \) in order to get the total energy loss by the parcel. Since the second term of Eq. 5.68 is the difference in flux of the gas and the gas only can move up, then that term needs to be multiplied with the surface \( Q \) normal to the velocity \( v \). By multiplying with those geometric factors we get:

\[ -\frac{16}{3} \frac{\sigma T^4}{\kappa \rho H_p} \frac{l_m}{d} (\nabla^* - \nabla_p) = \frac{Q \rho c_p v T_{l_m}}{2 H_p} (\nabla_{ad} - \nabla_p) \]  

(5.70)

\[ (\nabla_p - \nabla_{ad}) = \frac{32 \sigma T^3}{3 \kappa \rho^2 c_p v} \frac{S}{dQ} (\nabla^* - \nabla_p) \]  

(5.71)

We now finally just need to figure out how fast the parcel rises so that we can find the convective flux.

**Exercise 5.10:**
Calculate the geometric factor \( S/(dQ) \) for a spherical parcel with radius \( r_p \)

**The convective velocity**

After having found the temperature difference between the convective parcel we need to find its rise-velocity in order to be able to use Eq. 5.62.
If we look at a buoyant parcel, then the buoyancy force working on it is just the gravitational force working on the difference in density:

\[ f_B = -g \frac{\Delta \rho}{\rho} \quad (5.72) \]

and taking into account that the expression is per unit mass, so we need to divide by the density. The work the buoyancy force produces is just the buoyancy force times the distance over which it works. The parcel we are looking at cannot turn all the work it is subjected to into acceleration, since it also needs to push gas in front of it away while it rises. If we assume that half the work produced by the buoyancy force is used to accelerate the parcel and since we already have assumed that it moves a distance \( \delta r \), then

\[ \frac{1}{2} f_B \delta r = -\frac{g}{2} \frac{\Delta \rho}{\rho} \delta r = \frac{g}{2} \frac{\Delta T}{T} \delta r = \frac{g}{2T} \frac{\delta r}{H_P} (\nabla^* - \nabla_p) (\delta r) \quad (5.73) \]

where Eq. 5.19 and the fact that there is no change in pressure compared to the outside \( (dP = 0) \) has been used. That amount of work is then equal to the kinetic energy of the parcel (remember again that all of these expressions are per unit mass):

\[ \frac{1}{2} v^2 = \frac{g}{2H_P} (\nabla^* - \nabla_p) (\delta r)^2 \quad (5.75) \]

\[ v = \sqrt{\frac{g}{H_P} (\nabla^* - \nabla_p)^{1/2} (\delta r)} \]

\[ = \sqrt{\frac{g}{4H_P} (\nabla^* - \nabla_p)^{1/2}} \quad (5.76) \]

We can insert that into Eq. 5.71 to get

\[ (\nabla_p - \nabla_{ad}) = \frac{32\sigma T^3}{3\kappa \rho^2 c_P} \sqrt{\frac{4H_P}{g\delta}} \left( \frac{S}{dQlm} \right) (\nabla^* - \nabla_p)^{1/2} \]

\[ = \frac{64\sigma T^3}{3\kappa \rho^2 c_P} \sqrt{\frac{H_P}{g\delta}} \left( \frac{S}{dQlm} \right) (\nabla^* - \nabla_p)^{1/2} \quad (5.77) \]

so finally inserting into Eq. 5.67, we get

\[ F_C = \rho c_P \sqrt{\frac{g\delta l_m}{2H_P}} \left( \frac{Tl_m}{2H_P} \right) (\nabla^* - \nabla_p)^{1/2} \]

\[ = \rho c_P T \sqrt{g\delta H_P^2} \left( \frac{l_m}{2} \right)^2 (\nabla^* - \nabla_p)^{3/2} \quad (5.78) \]
So now we can find the energy flux and through that the temperature gradient our star has in the convection zone by using that the total flux is

\[ F_R + F_C = \frac{16\sigma T^4}{3k\rho H_P} \nabla_{\text{stable}} \]  

(5.79)

where \( \nabla_{\text{rad}} \) is the temperature gradient needed for all the energy to be carried by radiation. In reality the radiative flux is

\[ F_R = \frac{16\sigma T^4}{3k\rho H_P} \nabla \]  

(5.80)

where the \( \nabla \) now is the actual temperature gradient. These two equations combined with Eq. 5.71 and Eq. 5.78 the temperature gradient of the star can be found.

So far we have encountered four different temperature gradients: \( \nabla_p \), \( \nabla_{\text{stable}} \), \( \nabla_{\text{ad}} \) and \( \nabla^* \). The relations between these gradients have so far been quite involved, but we can say something about their relative sizes. Pressure and temperature both decreases with radius so the gradients are all positive. If we furthermore look at a convectively unstable layer, then we already know from Eq. 5.58 that \( \nabla_p > \nabla_{\text{ad}} \). Since for a convective gas, some of the energy is now moved through convection, the temperature gradient does not need to be as steep as in the case where all the energy has to move by radiation, so \( \nabla^* < \nabla_{\text{stable}} \). For a rising parcel of gas we know that it cools both by adiabatic expansion and by radiative losses, so the temperature must decrease faster than for a parcel which only cools by adiabatic expansion alone, i.e. \( \nabla_p > \nabla_{\text{ad}} \). Finally we know that for a rising parcel, the temperature has to decrease slower than the surroundings, otherwise it would become unable to rise very quickly, so \( \nabla_p < \nabla^* \). Combining these we get

\[ \nabla_{\text{stable}} > \nabla^* > \nabla_p > \nabla_{\text{ad}} \]  

(5.81)

**Exercise 5.11:**

Insert Eq. 5.78 and Eq. 5.80 into Eq. 5.79 to get an expression that contains an expression for \( \left( \nabla^* - \nabla_p \right) \) as a function of \( \nabla^* \) and \( \nabla_{\text{stable}} \).

*Hint: If you can insert the expression for the pressure scale height (you found it in Exerc. 5.9) and end up with only known quantities for the gas, i.e. \( \sigma, T, \kappa, \rho, c_P, g \) and \( \delta \) in the expression, as well as the \( \nabla \)’s.*
CHAPTER 5. ENERGY TRANSPORT

Exercise 5.12:  
Insert Eq. 5.71 into

\[(\nabla_p - \nabla_{ad}) = (\nabla^* - \nabla_{ad}) - (\nabla^* - \nabla_p)\]

and use Eq. 5.76, to get a second order equation for \((\nabla^* - \nabla_p)^{1/2}\). Express the solution \(\xi\) to the resulting equation as a function of \(\nabla^*, \nabla_{ad}\), \(U\) and the geometrical constant in front of \(U\) in the equation above, where

\[U = \frac{64\sigma T^3}{3k\rho^2 c_p}\sqrt{\frac{H_p}{g\delta}}\]

Argue why this equation has only one viable solution.

Exercise 5.13:  
Use your solution to Exerc. 5.12 into your solution of Exerc. 5.11 to eliminate \(\nabla\) except in the form of \(\xi\) used in Exerc. 5.12.

There is still one free parameter left, which we have not determined: \(l_m\). One can give physical arguments for one value or another, but all in all, it is a free parameter that can be tuned to any value that suits the application. Generally it is assumed that

\[l_m = \alpha H_p\]  \hspace{1cm} (5.82)

where \(\alpha\) is a parameter between \(1/2\) and 2, again this is a free parameter, but at least slightly better constrained than \(l_m\). That is not satisfying in the strictest sense, but a complete treatment of convection takes full compressible hydrodynamics simulations for some cases even magneto hydrodynamic simulations, which are computationally very expensive to complete. The theory behind hydrodynamics and magneto hydrodynamics will be treated later in these notes.

Example 5.1:  
Inserting values for the middle of the convection zone, assuming that
5.3. CONVECTIVE TRANSPORT

the gas is ideal and using the following values:

\[ \mu = 0.6 \]
\[ T = 0.9 \times 10^6 \text{ K} \]
\[ \rho = 55.9 \text{ kg m}^{-3} \]
\[ R = 0.84 R_\odot \]
\[ M(R) = 0.99 M_\odot \]
\[ \kappa = 3.98 \text{ m}^2 \text{ kg}^{-1} \]
\[ \alpha = 1 \]

then for purely radiative transport the following values can be found

\[ \nabla_{\text{stable}} = 3.26 \]
\[ \nabla_{\text{ad}} = \frac{2}{5} \]

so the gas is unstable, so the value for \( \nabla \) (the temperature gradient which would be necessary for all the energy to be carried by radiation) cannot be used. Calculating the convective and radiative energy flux ratios then gives:

\[ H_p = 32.5 \text{ Mm} \]
\[ U = 5.94 \times 10^5 \]
\[ \xi = 1.175 \times 10^{-3} \]
\[ \nabla^* = 0.400 \]
\[ v_{\text{conv}} = 65.62 \text{ m s}^{-1} \]
\[ \frac{F_C}{F_C + F_{\text{Rad}}} = 0.88 \]
\[ \frac{F_{\text{Rad}}}{F_C + F_{\text{Rad}}} = 0.12 \]

A further check you should make is that Eq. 5.81 hold. In this case I have:

\[ \nabla_{\text{ad}} < \nabla_p < \nabla^* < \nabla_{\text{stable}} \]
\[ \frac{2}{\xi} < 0.400000 < 0.400001 < 3.26078 \]
In a physical sense we cannot write up this sort of expression, with such a precision, since most of the constants we use are not this precise, but in this case we use it only for internal consistency and as a mathematical check.
Chapter 6
Hydrodynamics

6.1 Introduction

Hydrodynamics is the science of fluids. It describes the movements of fluids under the influence of external forces. Fluid is to be understood in the broadest terms, including gasses and as we shall see ensembles of particles that do not initially makes us think of fluids.

The hydrodynamic equations consists of only a few seemingly simple equations that hide a possibly very complex behavior. Especially one term in the equation of momentum gives rise to the complex behavior, which involves the transfer of momentum when a fluid package is stressed. The stress tensor term will be dealt with in detail to give a sense of the behavior to expect from that term under different conditions.

The fluid equations can be derived completely from statistical mechanics, but that is outside the scope of these notes. We will refer to more complete works on statistical mechanics instead, of which there are several. Sometimes results from statistical mechanics will be used, without giving the full derivation of the equations, but a short explanation of the equation will be given, that hopefully will make the equations look sensible.

6.2 Definition of a fluid

Hydrodynamics is a simplification of the full particle treatment of a large ensemble of particles. In general the main requirement of a medium to qualify as a fluid is that it can be split into volume elements which can be
represented by a continuous function $\rho$ defined as
\[
\rho \, dV = \sum_{dV} m
\] (6.1)

with $\rho$ being defined as the density of the fluid, $dV$ is a small volume element and $m$ is the mass of the individual particles that make up the fluid. If the mean free path of the particles are smaller than the typical diameter of the volume $dV$ it is possible to create a meaningful mean velocity and energy of the particles inside $dV$, and also define $\rho$ as done above. If this volume element is smaller than the relevant scales we are interested in the medium can be well approximated by hydrodynamics. If that is not true, then the medium we are looking at cannot be treated as a fluid. Another definition of a fluid involves the Knudsen\(^1\) number:
\[
Kn = \frac{\lambda}{L}
\] (6.2)

where $\lambda$ is the mean free length between collisions for the particles in the fluid, while $L$ is the typical scale of the system. The Knudsen number must be smaller than one (in general much smaller) for a fluid description to be valid. The Knudsen number is usually the number that is used since Eq. 6.1 is not as easily used in day to day work.

An example of a “fluid” is a large number of balloons, incased in a sports stadium with an average distance between them of one meter, then the Knudsen number would be $Kn = 1/100$ so as long one didn’t look at scales much smaller than the scale of the stadium, they would behave as a fluid.

For neutral particles, the mean free path is given exactly as for photons
\[
\lambda = \frac{1}{n\sigma}
\] (6.3)

where here $\sigma$ is the scattering cross section, which typically is $10^{-19}$ m\(^2\) for atomic particles and molecules and $n$ is the number density of the particles, which for air at ground level is roughly $10^{25}$ m\(^{-3}\), giving $\lambda \sim 10^{-6}$ m in the air surrounding us. That means that as long as we do not look at scales larger than roughly a tenth of a millimeter the Knudsen number will be less than 0.01, and so we can treat the air as a fluid.

If we use the same numbers for the interior of the sun, then $\sigma$ is still roughly the same, while the number density at the bottom of the convective

---

\(^1\)Martin Knudsen(1871–1949) was an engineer working primary on molecular gas flow at low pressure.
6.3. FROM PARTICLES TO FLUID

zone is roughly \(10^{31} \text{ m}^{-3}\), so \(\lambda \sim 10^{-12} \text{ m}\) making the fluid approximation very applicable.

At the surface of the sun, in the photosphere, the number density is roughly \(10^{23} \text{ m}^{-3}\), so that \(\lambda \sim 10^{-4} \text{ m}\) and again we can safely treat all relevant scales at the solar surface as a fluid (the typical scale at the solar surface is \(1 \text{ Mm} = 10^6 \text{ m}\)).

Exercise 6.1:
In this exercise consider the sun as a particle. The collisional cross section of the sun is not given by only the solar radius, but a a much larger radius, due to the gravitational pull exerted by the sun. Estimate the radius where the gravitational potential of the sun has decreased by a factor \(1/e\) compared to the gravitational potential at the solar surface and use that for calculating the collisional cross section. If our galaxy consisted of stars identical to our sun with the same collisional cross section, would the movements of stars then be considered to be governed by hydrodynamics? Would galaxies in a galaxy cluster?

Hint: Find a rough number for the number of stars in the milky way and assume that the milky way is a disc with a radius of 20 kpc and a thickness of 0.5 kpc. For the galaxy cluster, you can for example use the local group of galaxies and assume that all the galaxies in the local group are identical to the milky way and distributed homogeneously in a sphere. For the galaxies you do not need to assume that the collisional cross section is larger than the physical radius, and you can assume that the galaxies are spherical with the same radius as the milky way.

6.3 FROM PARTICLES TO FLUID

When being certain that the gas or liquid under investigation actually behaves like a fluid, it is time to look at the equations that govern the dynamics of a fluid, regardless of whether it is a collection of molecules, the water in our oceans or the molecular gas in our galaxy.

6.3.1 Hydrostatics

Hydrostatics is a sub branch of hydrodynamics that only deals with fluids at rest. There are a number of simplifications that can be made and the only equation is that of momentum, including all the external body forces.
CHAPTER 6. HYDRODYNAMICS

working on the fluid:

\[
\frac{\partial \rho \mathbf{u}}{\partial t} + \nabla \cdot (\rho \mathbf{u} \mathbf{u}) = -\nabla P + \mathcal{F} \tag{6.4}
\]

where \( \mathbf{u} \) is the velocity vector. In hydrostatics there are no velocities so this equation is further simplified by the left hand side being zero. So here is only the balancing of body forces working on a fluid parcel. Most often the main body force is gravitation, which just gives:

\[
\nabla P = -\frac{G \rho m}{r^2} \tag{6.5}
\]

where \( m \) is the mass inside the radius \( r \). Hydrostatics are not really a part of hydrodynamics, which is quite clear from the names, but often it is the transition from a dynamic region to a static region which gives problems, as there usually are large gradients, and always instabilities evolving which can only be treated by a hydrodynamic treatment. Such a place is the transition from the radiative zone to the convective zone in the sun. If modeling that region, it is necessary to include a region that theoretically would be static, but because there is a dynamic layer just above, instabilities and down flows penetrate into the static region – making it non-static.

6.3.2 The continuity equation

The continuity equation, which in most cases is refereed to as the equation of conservation of mass. It describes any effects that might add or remove mass from the volume being modeled. Often there are no such sinks or sources present and the equation turns into an equation describing the conservation of mass

\[
\frac{\partial \rho}{\partial t} + \frac{\partial \rho \mathbf{u}}{\partial x} = \mathcal{S} \tag{6.6}
\]

where \( \mathcal{S} \) is source or sink terms. In vector notation which we will use to a large degree the equation reads

\[
\frac{\partial \rho}{\partial t} + \mathbf{r} \cdot \left( \rho \mathbf{u} \right) = \mathcal{S} \tag{6.7}
\]

By setting \( \mathcal{S} \) to zero, doing the divergence of the second term and dividing by \( \rho \), one can rewrite the equation to read

\[
\frac{1}{\rho} \frac{D \rho}{D t} = -\nabla \cdot \mathbf{u} \tag{6.8}
\]
where a new operator has been defined:

\[
\frac{D}{Dt} = \frac{\partial}{\partial t} + \mathbf{u} \cdot \nabla
\]  

(6.9)

which is called the substantial derivative, and describes the evolution at a point following the fluid, in contrast to the \( \partial/\partial t \) which describes changes at a set location in space.

### 6.3.3 The equation of motion

The momentum equation of equation of motion is an equation we have already used in Chap. 5, and also used in Sec. 6.3.1, and describes the change in velocity the fluid experience when being the subject of external and internal forces. The equation contains a term that looks simple, but is the principle complication when trying to model a fluid. If we look at the equation coming directly from statistical mechanics, then for an ensemble of particles we have

\[
\frac{\partial (\rho u_i)}{\partial t} + \frac{\partial}{\partial x_k} (\rho \langle v_i v_k \rangle) - \mathcal{F} = 0
\]  

(6.10)

where the subscripts defines the direction, \( v \) is the velocity of the individual particles and \( \langle ... \rangle \) is the number weighted average of the particles. The second term of this equation is the effects that pass through the boundaries of the volume we are looking at while \( \mathcal{F} \) is the body forces working on the whole of the volume, as for instance gravity.

We now decompose the particle velocity in two parts

\[
v_i = u_i + w_i
\]  

(6.11)

where \( w_i \) is the difference between the bulk velocity \( u_i \) and the particle velocity \( v_i \). That way we can write

\[
\langle v_i v_k \rangle = u_i u_k + \langle w_i w_k \rangle
\]  

(6.12)

by using that the average of all the particles individual velocities \( v_i \) should give the bulk velocity \( u_i \), then it follows that \( \langle w_i \rangle = 0 \). Eq. 6.10 can now be rewritten

\[
\frac{\partial \rho u_i}{\partial t} + \frac{\partial}{\partial x_k} \left( \rho \frac{\partial u_i}{\partial x_k} + \rho \langle \omega_i \omega_k \rangle \right) - \mathcal{F} = 0
\]  

(6.13)

If we look at the first part of second term on the left side of Eq. 6.13 (the term called “advection”) and see what physics that term stands for, then
the isolated $x$ component reads ($i = x$):

$$
\frac{\partial}{\partial x_k} (\rho u_x u_k) = \frac{\partial}{\partial x} (\rho u_x^2) + \frac{\partial}{\partial y} (\rho u_x u_y) + \frac{\partial}{\partial z} (\rho u_x u_z)
+ \frac{\partial}{\partial x} (\rho u_x^2) + \rho u_x \frac{\partial u_x}{\partial y} + u_y \frac{\partial \rho u_x}{\partial y}
+ \rho u_x \frac{\partial u_z}{\partial z} + u_z \frac{\partial \rho u_x}{\partial z}
= \rho u_x \left( \frac{\partial u_x}{\partial x} + \frac{\partial u_y}{\partial y} + \frac{\partial u_z}{\partial z} \right)
+ \left( u_x \frac{\partial \rho u_x}{\partial x} + u_y \frac{\partial \rho u_x}{\partial y} + u_z \frac{\partial \rho u_x}{\partial z} \right) (6.14)
$$

The terms are quite easy to understand. The first term describes the change in the $x$ directed momentum due to the difference in the velocities advecting momentum into and out of the volume. The second term is then the change in $x$-directed momentum due to a difference in the momentum advected through the walls of the volume.

**Exercise 6.2:**
Insert Eq. 6.11 into the term $\langle v_i v_j \rangle$ and show that the result is Eq. 6.12, by using that $\langle w_i \rangle = \langle w_j \rangle = 0$

We can now split up the second part of the second term of Eq. 6.13 (called the “stress tensor”) into a diagonal and a non-diagonal part

$$
\rho \langle w_i w_k \rangle = P \delta_{ik} - \tau_{ik} (6.15)
$$

where $\tau_{ik}$ is the viscous stress tensor and $P$ is the diagonal part of the stress tensor $\langle w_i w_k \rangle$ and is the well known thermal pressure and is given by

$$
P = \frac{1}{3} \rho \langle |w|^2 \rangle (6.16)
$$

where the expression $\langle |w| \rangle$ means the norm of the trace of the tensor $\langle w_i w_k \rangle$. While the terms in the viscous stress tensor are

$$
\tau_{ik} = \rho \langle \frac{1}{3} |w|^2 \delta_{ik} - w_i w_k \rangle (6.17)
$$

and these terms are the ones creating many of the interesting and complex behaviors seen in fluid dynamics. The whole of the momentum equation now becomes

$$
\frac{\partial (\rho u_i)}{\partial t} = - \frac{\partial}{\partial x_k} (\rho u_i u_k + P \delta_{ik} - \tau_{ik}) + F (6.18)
$$
This equation can look a bit intimidating at first, so let’s look at the one of the symmetric components: where \( i = x \) and \( k = x \)

\[
\frac{\partial \rho u_x}{\partial t} = -\frac{\partial}{\partial x} \left( \rho u_x^2 + P - \tau_{xx} \right) + \mathcal{F}
\]

\[
= -\frac{\partial}{\partial x} \left( \rho u_x^2 + \frac{1}{2} \rho \left( \langle |w|^2 \rangle - \rho \langle \frac{1}{2} |w|^2 - \frac{1}{2} |w|^2 \rangle \right) \right) + \mathcal{F} \quad (6.19)
\]

If the average deviation from the main flow is the same in all directions (which it should be according to the definition of \( w_i \)) then

\[
\langle w_x^2 \rangle = \langle w_y^2 \rangle = \langle w_z^2 \rangle \quad (6.20)
\]

and so Eq. 6.19 then just becomes

\[
\frac{\partial \rho u_x}{\partial t} = -\frac{\partial}{\partial x} \left( \rho u_x^2 + P - \rho \langle \frac{1}{2} |w|^2 - \frac{1}{2} |w|^2 \rangle \right) + \mathcal{F}
\]

\[
= -\frac{\partial}{\partial x} \left( \rho u_x^2 + P \right) + \mathcal{F} \quad (6.21)
\]

in other words, there is only the advection of the momentum and the well known pressure to take care of. The asymmetric part is easier understood if we move away from the particle picture and try to understand the physical effect of the viscous stress tensor. The asymmetric stress tensor clearly transfers momentum from one direction to another. If we transfer coordinate system, the transfer of momentum should not change, so the stress tensor must be symmetric. Physically we know intuitively that a fluid moving at constant speed with no gradients in the velocity, should not transfer momentum to other directions, i.e. a flow which is along \( x \) should not suddenly start flowing along \( y \) or \( z \) just due to internal friction. So the viscous stress tensor clearly cannot have terms depending on the velocity, because that would lead to exactly such an effect. So we are left with terms containing derivatives of the velocity, which are symmetric. Another constraint comes from the imagining a fluid rotating like a solid body, there should again be no internal friction because a fluid element sees no gradients in velocity, even though there are gradients in a coordinate system that does not rotate with the fluid. We are finally left with terms that look like

\[
\langle w_i w_k \rangle = \eta \left( \frac{\partial u_i}{\partial x_k} + \frac{\partial u_k}{\partial x_i} \right) \quad (6.22)
\]
because these are symmetric and they provide no non-constant terms for rotations of the form
\[ \boldsymbol{\Omega} \times \mathbf{r} \] (6.23)

Exercise 6.3:
Show that the form of the tensor \( w_i w_k \) gives no non-constant terms for a solidly rotating cylinder. Begin by using cylindrical coordinates and remember that the calculating gradients in cylindrical coordinates introduces some extra factors in the expressions. Write down the expressions for \( u_\omega \) and \( u_r \) for a solid rotating cylinder aligned with the \( z \) axis (i.e., no gradients in along \( z \)). Assume that the cylinder is infinitely wide in the \( r-\omega \) plane. Then calculate the asymmetric terms in \( \tau_{ik} \) and see if the contribution to the momentum equation is zero.

If we look at what physical effect terms like these provide in the equation for the momentum, then let's look at the case where \( i = x \), and \( k \) takes all the directions possible, and there are no body-forces:

\[
\frac{\partial \rho u_x}{\partial t} = -\rho u_x \frac{\partial u_x}{\partial x} - u_x \frac{\partial \rho u_x}{\partial x} - \frac{\partial P}{\partial x} - \rho u_x \frac{\partial u_y}{\partial y} - u_y \frac{\partial \rho u_x}{\partial y} - \frac{\partial}{\partial y} \left( -\eta \frac{\partial u_x}{\partial y} - \eta \frac{\partial u_y}{\partial x} \right) - \rho u_x \frac{\partial u_z}{\partial z} - u_z \frac{\partial \rho u_x}{\partial z} - \frac{\partial}{\partial z} \left( -\eta \frac{\partial u_x}{\partial z} - \eta \frac{\partial u_z}{\partial x} \right) \]

(6.24)

This equation seems again a bit intimidating, but let's look at the physics. We already know that the two first terms on each line represents \( x \)-directed momentum being advected into the volume we are looking at due to either a gradient in the \( x \)-momentum, or a gradient in the advecting velocity. The last term in the first line is also easy to understand, it's just the thermal pressure, so we are left with the last term on the second and third line. Let's look at the second line. The terms are double gradients, so the terms deal with a gradient of a gradient, which is not always easy to picture. In order not to complicate the picture too much, assume that the density is constant (a very gross simplification for astrophysics, but is the standard assumption in meteorology) and assume further that there are only two dimensions \( x \) and \( y \). There are now two separate terms we need to look at:

\[
\frac{\partial^2 u_x}{\partial y^2} \quad \text{and} \quad \frac{\partial^2 u_y}{\partial x \partial y} \]

(6.25)
The terms can best be understood if we look at them separately. The first term is a double gradient in the $y$–direction, so let’s imagine a flow which is directed along the $x$–axis and symmetric around $y = 0$ with a maximum at $y = 0$ (see Fig. 6.1). The internal friction in the fluid leads to the fast moving fluid at $y = 0$ is decelerated while the slower moving fluid next to it is being accelerated. In the end this effect by itself will lead to all the fluid moving at the same speed.

The second term of Eq. 6.25 is more complex. Here we are dealing with a double gradient in two different directions. Fig. 6.2 shows a flow with gradients in two directions. The effect of this term is now easier to understand, and partially comes because of mass conservation, but it is due to internal friction. The term makes the beam become narrower and narrower, and will continue to do so until other processes take over. The simple example of Fig. 6.2 is of course not realistic for very long if the mass density is to be constant, since the inner parts of the flow will be more and more tenuous because of the acceleration.

If we had not assumed $\rho$ to be constant, then we would have another set of terms in the viscous stress tensor which deals with the gradients in both density and velocity. Those terms will not be treated here, but they are taking care of the number of collisions between particles in the flow directions. Imagine for instance that while looking at the first of the terms here, but that the density also varied such that the density was low at low $y$ and high at high $y$. There would be fewer collisions at low $y$ than at high $y$, so the flows ability to feel the internal friction would be lower at low $y$ than at high $y$, and consequently that would affect the internal friction in the fluid.
Exercise 6.4:
So far we have assumed the density to be constant. That removes some of the terms in the expression

\[
\frac{\partial \rho u_x}{\partial t} = \ldots - \frac{\partial}{\partial y} \left( -\eta \rho \frac{\partial u_x}{\partial y} - \eta \rho \frac{\partial u_y}{\partial x} \right) = \frac{\partial}{\partial z} \left( -\eta \rho \frac{\partial u_x}{\partial z} - \eta \rho \frac{\partial u_z}{\partial x} \right)
\]

from Eq. 6.24. We have so far assumed that the density to be constant but now assume that the density is not constant. By using the chain rule this produces the the terms we have just looked at and but also terms that includes the gradient of the density. Give an example of when these terms are non zero and explain what the physical effect these terms have.

6.4 Waves in Hydrodynamics

Waves are always grouped according to what their restoring force/forces is/are. There are in principle only one type of waves in pure hydrodynamics. If more body forces are introduced in Eq. 6.4, then more types of waves can be produced, but here only the pure wave-modes will be explained. In the case that the fluid is almost at rest and in equilibrium, then we make the assumption that any changes in the pressure and density are only small:

\[\rho = \rho_0 + \rho'\] \[P = P_0 + P'\]

where the subscript 0 means an unchanging equilibrium value, while the superscript ′ means a small perturbation on top of that. Since we are looking at small perturbations, it is also safe to assume that the velocity is small, so when looking at the continuity equation (Eq. 6.6)
in one dimension it can be written:

\[
\begin{align*}
\frac{\partial \rho}{\partial t} &= \frac{\partial \rho u_x}{\partial x} \\
\frac{\partial \rho_0 + \rho'}{\partial t} &= -\frac{\partial (\rho_0 + \rho') u_x}{\partial x} \quad (6.26) \\
\frac{\partial \rho'}{\partial t} &= -\rho_0 \frac{\partial u_x}{\partial x} \quad (6.27)
\end{align*}
\]

where the step from Eq. 6.26 to Eq. 6.27 is true to first order. The argument is that terms that containing two small numbers multiplied with each other are so small compared with the others, that can be ignored. The numbers with subscript 0 are constants so can be moved outside the differentials. The same can be done for the equation of motion, giving

\[
\begin{align*}
\frac{\partial \rho u_x}{\partial t} &= -\frac{\partial}{\partial x} \left[ \rho u_x^2 + P \right] \\
\rho_0 \frac{\partial u_x}{\partial t} &= -\frac{\partial P'}{\partial x} \quad (6.28)
\end{align*}
\]

**Exercise 6.5:**

Make the same assumptions made to reach Eq. 6.27 to prove Eq. 6.28

We are now left with three unknowns \( \rho', P', \) and \( u_x \), and since we only have two equations we have to get rid of one of them. For small perturbations in an ideal fluid, we can assume that a small perturbation in the pressure is due to a small perturbation in the density at constant entropy. Writing that as

\[
P' = \left( \frac{\partial P_0}{\partial \rho_0} \right)_s \rho' \quad (6.29)
\]

we can insert Eq. 6.29 into Eq. 6.27 to get

\[
\begin{align*}
\frac{\partial}{\partial t} \left[ P' \left( \frac{\partial \rho_0}{\partial P_0} \right)_s \right] &= -\rho_0 \frac{\partial u_x}{\partial x} \\
\left( \frac{\partial \rho_0}{\partial P_0} \right)_s \frac{\partial P'}{\partial t} + P' \frac{\partial}{\partial t} \left( \frac{\partial \rho_0}{\partial P_0} \right)_s &= -\rho_0 \frac{\partial u_x}{\partial x} \quad (6.30)
\end{align*}
\]

\[
\frac{\partial P'}{\partial t} = -\rho_0 \left( \frac{\partial P_0}{\partial \rho_0} \right)_s \frac{\partial u_x}{\partial x} \quad (6.31)
\]

where the step from Eq. 6.30 to Eq. 6.31 is due to the the term \( \frac{\partial \rho_0}{\partial P_0} \) is set by the equation of state, which is not dependent on time, but only a function
of the gas composition. We now have two equations with two unknowns: $P'$ and $\rho'$. If we introduce the velocity potential $u_x = \frac{\partial \phi}{\partial x}$, then Eq. 6.28 becomes

$$P' = -\rho_0 \frac{\partial \phi}{\partial t}$$

(6.32)

**Exercise 6.6:**

Show that Eq. 6.28 becomes Eq. 6.32 when introducing a velocity potential.

Inserting Eq. 6.32 into Eq. 6.31 it gives

$$\frac{\partial^2 \phi}{\partial t^2} - \left( \frac{\partial P_0}{\partial \rho_0} \right)_s \frac{\partial^2 \phi}{\partial x^2} = 0$$

(6.33)

Equations of this form is called a wave equation, where

$$c_s^2 = \left( \frac{\partial P_0}{\partial \rho_0} \right)_s$$

(6.34)

where $c_s$ is the wave speed. Looking back to Chap. 5.3.2 we find that for an ideal gas

$$c_s^2 = \left( \frac{\partial P_0}{\partial \rho_0} \right)_s = \gamma \frac{P}{\rho}$$

(6.35)

If we substitute $\eta = x + c_s t$ and $\xi = x - c_s t$, then Eq. 6.33 can be rewritten

$$\frac{\partial^2 \phi}{\partial t^2} - c_s^2 \frac{\partial^2 \phi}{\partial x^2} = 0$$

(6.36)

$$\frac{\partial^2 \phi}{\partial \eta \partial \xi} \frac{\partial \eta}{\partial t} \frac{\partial \xi}{\partial t} - c_s^2 \frac{\partial^2 \phi}{\partial \eta \partial x} \frac{\partial \eta}{\partial t} \frac{\partial x}{\partial t} = 0$$

(6.37)

$$\frac{\partial^2 \phi}{\partial \eta \partial \xi} \left(-c_s\right) - c_s^2 \frac{\partial^2 \phi}{\partial \eta \partial \xi} = 0$$

(6.38)

$$\frac{\partial^2 \phi}{\partial \eta \partial \xi} = 0$$

(6.39)

Integrating this with respect to $\xi$ gives $\frac{\partial \phi}{\partial \eta} = F(\eta)$ where $F(\eta)$ is an arbitrary function of $\eta$. Integrating again, this time with respect to $\eta$ we get $\phi = f_1(\eta) + f_2(\xi)$ where now $f_1$ and $f_2$ are arbitrary functions of their arguments. Writing this in full we simply have

$$\phi = f_1(x + c_s t) + f_2(x - c_s t)$$

(6.40)
and if we continue in the same way for density and pressure, we get expressions of the same form. For instance let’s look at the density \( \rho' = f_1(x + c_s t) + f_2(x - c_s t) \) and let’s assume that \( f_2 = 0 \). Then \( \rho' = f_1(x + c_s t) \), and so the density is the same as long as \( x + c_s t \) is constant. So assume that the density has a certain value at a specific point in space \( x \) at \( t = 0 \), then at a later time, the density will have the same value at a point which is shifted along \( x \) by \( c_s t \). As this is true for all positions, then it means that the whole profile of the density is just shifted in space by \( c_s t \). As the only force that can drive this motion is pressure, the waves described by Eq. 6.33 is a pressure wave, which is also called a sound wave, and the pressure/density wave moves with the speed of sound \( c_s \).

**Exercise 6.7:**
Calculate the speed of sound in the solar photosphere, and the solar corona, assuming the gas there to be an ideal gas. (Use the physical values you need from the appendix.)
Chapter 7

Magnetohydrodynamics

7.1 Introduction

Magneto hydrodynamics is an extension to hydrodynamics. Magneto hydrodynamics is the physics of electrically conducting fluids. As it turns out, the equations governing the electric and magnetic fields in such a fluid can be greatly simplified if the fluid is highly conductive, the fluid consists of particles which collide often and finally that there is on average as many negative as positive charges in the fluid. MHD is used almost everywhere in astrophysics, as magnetic fields are almost present everywhere. The magnetic field of the earth are known from everyday use when we look at a compass that point towards the magnetic north pole. The strength of the magnetic field at the earths surface is roughly $0.5 \, \text{G} = 5 \cdot 10^{-5} \, \text{T}$. The solar surface has concentrations of magnetic fields in sun spots with magnetic field strengths of roughly $2 \cdot 10^3 \, \text{G} = 0.2 \, \text{T}$ or roughly 4000 times stronger. But the sun is a relatively quiescent star, while young stars generally have stronger magnetic fields. The most extreme magnetic fields are found around a subset of neutron stars with immensely strong magnetic fields of $10^{15} \, \text{G}$ called magnetars. As we shall see, all these astrophysical magnetic fields can completely dominate the dynamics of the gas and so MHD is necessary in order to understand the physics.

7.2 The assumption of MHD

MHD depends on a number of simplifications, just as HD does. The simplifications used in MHD are of electro-dynamic character. They come about because of the asymmetry between electric and magnetic fields. That asym-
7.2. THE ASSUMPTION OF MHD

metry is easily understood because we have a large amount of electrically charged particles but we have so far not found any magnetic monopole particles. We also know that on large scales there seems to be no net electric charge, i.e. the universe seems to contain equal amounts of electrically positive and negatively charged particles. The consequence is that electric fields are on large scales rather small, while magnetic fields can easily be present. In almost all places in the universe, there will be a number of free electrons due to for instance UV radiation\(^1\). Even the almost neutral solar photosphere has enough free electrons from carbon and the alkali metals, to cancel the build up of any electric field.

A gas which contains a number of charge carriers large enough to affect the gas dynamics is called a plasma, and conditions for when a gas becomes a plasma is considered later. In this beginning phase it is enough to consider a gas where all ions have lost all of their electrons, so that all ions have a positive charge equal to their atomic number and that their free electrons are still in the neighbourhood. That implies that

\[
\sum_i Z_in_i = n_e
\]

(7.1)

where \(Z_i\) is the atomic charge number, \(n_i\) is the number density of that atom and \(n_e\) is the number density of electrons. If we now look at one specific ion then it will set up an electro static potential that is

\[
\nabla^2 \phi = -\frac{1}{\epsilon_0} \rho_e
\]

(7.2)

where \(\rho_e\) is the charge density distribution which includes both the ion at the centre and the surrounding electrons and ions. The charge density will be given by

\[
\rho_e = Z_ie\delta(r) - n_ee \exp \left( -e\phi/kT \right) + n_iZ_i e \exp \left( Z_i e\phi/kT \right)
\]

(7.3)

which consist of the ion (first term), the electrons (second term) and the surrounding ions (third term). The term describing the ion has a delta function \(\delta(r)\) which is infinite at \(r = 0\) and zero otherwise, and when it is integrated it has the value one at \(r = 0\). The electron number density \(n_e\) and ion number density \(n_i\) is the number densities in the absence of the central

\(^1\)Exceptions are the internal regions of very cold interstellar clouds, which can be completely screened from UV radiation, and cold planetary atmospheres where lightening is the effect of the build up of electric field.
CHAPTER 7. MHD

ion we are looking at. By using the power expansion for the exponential function:

\[ \exp(x) = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \ldots \] (7.4)

and keeping only the two first terms, then Eq. 7.3 becomes

\[ \rho_e = Z_i e \delta(r) - n_e e + n_i Z_i e - \frac{n_e e^2}{kT} - \frac{n_i Z_i^2 e^2}{kT} \]

\[ = Z_i e \delta(r) - \frac{e^2}{kT} (n_e + n_i Z_i^2) \phi \] (7.5)

and use it to write Eq. 7.2 as:

\[ \frac{1}{r^2} \frac{d}{dr} \left( r^2 \frac{d\phi}{dr} \right) = -\frac{Z_i e}{\epsilon_0} \delta(r) + \frac{e^2}{\epsilon_0 kT} (n_e + n_i Z_i^2) \phi \] (7.6)

where we use a spherical coordinate system, because the electric field is only dependent on the radius. The last term is a constant times the electric potential \( \phi \), and that constant has the dimension of inverse length squared and is called the Debye length:

\[ L_D^{-2} = \frac{e^2}{\epsilon_0 kT} (n_e + Z_i^2 n_i) \] (7.7)

Inserting that into Eq. 7.6 gives

\[ \frac{1}{r^2} \frac{d}{dr} \left( r^2 \frac{d\phi}{dr} \right) = -\frac{Z_i e}{\epsilon_0} \delta(r) + L_D^{-2} \phi \] (7.8)

**Exercise 7.1:**
Show that the unit of the second term on the right hand side of Eq. 7.5, disregarding the electric potential, is indeed inverse length squared.

**Exercise 7.2:**
Deduce Eq. 7.8

The solution to Eq. 7.8 has to satisfy \( \phi \to 0 \) as \( r \to \infty \) and \( \phi \to Z_i e/\epsilon_0 r \) when \( r \to 0 \). Since the solution also has to be symmetric in space, then a good guess is

\[ \phi = \frac{Z_i e}{\epsilon_0 r} \exp(-r/L_D) \] (7.9)
7.2. THE ASSUMPTION OF MHD

Exercise 7.3:
Show that Eq. 7.9 is a solution to Eq. 7.8 for \( r > 0 \) and that it satisfies \( \phi \to 0 \) as \( r \to \infty \) and \( \phi \to Z_e e/\epsilon_0 r \) when \( r \to 0 \).

Eq. 7.9 has a very clear physical interpretation. A potential set up by an ion (or more for that matter) is screened out exponentially by the surrounding electrons and ions with a characteristic length that is the Debye length. In order for us to be able to make the same simplification as we did when deducing the HD equations, we must now require that there are many charge carriers within the Debye sphere, so we must require that

\[
n_e L_D^3 >> 1 \quad (7.10)
\]

So if this requirement is met, there will be no large electric fields present, but at the same time, we cannot treat the gas as a collective in the same sense as we did in the equations for fluid mechanics, if we do not also limit our interest to scales which are much longer than the Debye length. Otherwise the electric and magnetic fields would be a patch work of small electric fields made up of a collection of small electric field contributions from individual ions and electrons.

As mentioned we can assume that on larger scale the fluid is neutral, but on small scales we cannot completely ignore electric fields, because it is possible for the electrons to move relative to the ions. Such movements would not violate the large scale neutrality, but would create electric currents. Such currents create magnetic fields as Ørsted’s famous experiment involving an electric current in a wire and compass, showing the direct connection between electric currents and magnetic fields. For particles moving in magnetic fields, they move in spirals – they gyrate around the magnetic field. The particles gyrate with a frequency called the Larmor frequency or cyclotron frequency

\[
\omega_L = \frac{qB}{mc} \quad (7.11)
\]

where \( q \) is the particle charge, \( B \) is the strength of the magnetic field, \( m \) is the particle mass and \( c \) is the speed of light. The exact Larmor frequency has an additional factor which of quantum mechanical nature, so Eq. 7.11 is for electrons which is the important one in this context. For a proton the gyro frequency is \( \sim 0.01 \text{s}^{-1} \) around a magnetic field with the magnetic field strength of \( 10^{-9} \text{T} \) (which is the typical value in interstellar clouds).

\[\textsuperscript{2}\text{Hans Christian Ørsted (1777-1851) was a famous danish scientist who investigated electricity, magnetism and acoustics, making the first experiment that showed a direct connection between electricity and magnetism}\]
Exercise 7.4:
Calculate the Larmor frequency for both electrons and protons in a solar sunspot, where the magnetic field strength is $\sim 0.1\, \text{T}$. The typical distance in the solar atmosphere is $\sim 1\, \text{Mm}$ (the typical size of structures in the solar atmosphere). What velocity is needed in order for the gyroradius $a = v/L$ to be comparable to that size?

Imagine now that we have a plasma inside a container, and that we now displace all the electrons to one side by a distance $dx$. Then the electric field we set up as a result of that displacement is

$$E = \frac{n_e e}{\epsilon_0} dx$$

(7.12)

which is the same electric field as the one between two capacitor plates because at one side of the container, there will be many electrons while at the other end of the container, there will be only ions. The equation of motion for an electron inside the container will now be

$$\frac{\partial v}{\partial t} = -\frac{eE}{m_e} = -\frac{n_e e^2}{\epsilon_0 m_e} dx = -\omega_{pe}^2 dx$$

(7.13)

where $\omega_{pe}$ is the electron plasma frequency, because Eq. 7.13 is the equation for a harmonic oscillator. So by displacing some of the charge carriers (electrons or ions), will make the other charge carriers oscillate around their position with a frequency which is the plasma frequency.

So far we have not included thermal motions – we have in principle assumed to plasma to be very cold. Introducing thermal motions we can see that the plasma frequency might not be all that interesting in case the thermal motions completely cancel out the displacement $dx$ assumed in Eq. 7.12, by fast movements. That effect is called Landau damping and simply means that if the charge-separation distance $dx$ is generally much smaller than the distance the particles travel due to their thermal motions, then the charge separation cannot keep waves alive. The electric field that the charge separation produces effectively disappears if the movement that produces the charge separation is much smaller than the thermal velocities. That means that if we look at plasma with high thermal velocities it is not possible to have charge separation.

Exercise 7.5:
Calculate the typical thermal velocities of electrons in the solar corona. Within one plasma frequency the electrons move from $+dx$ to $-dx$ and back compared to the ions. Assume that $dx = L_D$ and compare the
distance the electrons have moved to the distance the electrons move due to their thermal motions within the same amount of time. Is charge separation important in the solar corona? What about the solar photosphere?

*Use the compendium to get the solar parameters you need to complete this exercise*

### 7.3 The MHD equations

The MHD equations includes the HD equations, but now also includes a number of equations that describes the evolution of the electric and magnetic field. The foundation for those equation are Maxwells equations:

\[
\nabla \cdot \mathbf{E} = \frac{\rho_e}{\epsilon_0} \quad (7.14)
\]

\[
\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t} \quad (7.15)
\]

\[
\nabla \cdot \mathbf{B} = 0 \quad (7.16)
\]

\[
\nabla \times \mathbf{B} = \mu_0 \mathbf{j}_e + \mu_0 \epsilon_0 \frac{\partial \mathbf{E}}{\partial t} \quad (7.17)
\]

where \( \rho_e \) and \( \mathbf{j}_e \) is the electric charge and current densities, while \( \mathbf{E} \) and \( \mathbf{B} \) is the electric and magnetic vector fields. The two coefficients \( \mu_0 \) and \( \epsilon_0 \) are the permeability of vacuum and the permittivity of free space respectively. They represent the resistance to the inductance of a magnetic field and the resistance encountered when forming an electric field. As the magnetic and electric field are intimately connected, so are these two fundamental parameters:

\[
c = \frac{1}{\sqrt{\mu_0 \epsilon_0}} \quad (7.18)
\]

where \( c \) is the speed of light.

By taking the divergence of Amperes law (Eq. 7.17) and inserting the time derivative of Coulombs law (Eq. 7.14) and remembering that the divergence of the rotation of a vector field is always zero give the equation of charge conservation:

\[
\frac{\partial \rho_e}{\partial t} + \nabla \cdot \mathbf{j}_e = 0 \quad (7.19)
\]

To get to the MHD equations we assume a number of things. First of all we assume that time-variations are slow compared to the light travel time (the factor in front of the time derivative of the electric field is actually
1/e^2 – much smaller than the other term), which allows us to ignore the displacement current in Eq. 7.17 so that it is just

\[ \nabla \times \mathbf{B} = \mu_0 \mathbf{j}_e \quad (7.20) \]

That assumption that time evolution is slow could also lead us to believe that Eq. 7.15 could be treated in the same way, but that is not the case because if that was the case then there is nothing left to compare \( \nabla \times \mathbf{E} \) with. Another argument is that we know that the only way to create electric fields is to create charge separation, while magnetic fields are created by currents which can easily be very large. Eq. 7.20 states that magnetic fields are only created by electric currents. We can try to estimate how small drift velocities that can still produce magnetic fields as we observe them in our universe. As we have previously assumed, then the total positive and negative charges cancel out over large scales:

\[ \rho_e = \sum_i Z_i e n_i - e n_e = 0 \quad (7.21) \]

where \( Z_i \) is the atomic proton number for the ions with number density \( n_i \), and we have now simplified everything to only have one species of atoms present and assuming that these atoms are completely ionized. As we have already seen the charge neutrality does not mean that there can be no currents, it just requires a small difference in velocity between the ions and the electrons:

\[ \mathbf{j}_e = Z_i e n_i \mathbf{u}_i - e n_e \mathbf{u}_e = -e n_e \mathbf{u}' \quad (7.22) \]

where \( \mathbf{u}_i \) and \( \mathbf{u}_e \) is the velocity of the ions and electrons respectively and \( \mathbf{u}' = \mathbf{u}_e - \mathbf{u}_i \) is the difference in velocity between the ions and electrons. This difference in velocity can generally be shown to be extremely small for most astrophysical instances.

**Exercise 7.6:**
In the solar photosphere, magnetic fields can reach field strengths of \( 10^3 \) G and generally there electron number density is roughly \( 10^{23} \text{ m}^{-3} \). By using Eq. 7.22 and Eq. 7.20 and assuming that the typical length is 1 Mm, give a rough estimate of what the speed \( |\mathbf{u}'| \) needs to be in order to create the magnetic field strengths observed in the solar photosphere.

The velocities are generally so small that we assume that collisions will mean that in spite of their being electric currents created by a difference in the speed of the ions and electrons, we still assume that all the particles
(also neutral particles) can be assumed to have on single velocity. In order to get one of the final equations in MHD, we need to start by looking at the dynamics of the electrons in the rest frame of the ions. Remember that there are a small difference in velocity between the ions and electrons so for the electrons the equation of motion becomes:

\[
m_e \frac{d\tilde{u}'}{dt} = -e \left( \tilde{E} + \tilde{u}' \times \tilde{B} \right) - m_e \nu_e \tilde{u}'
\]  

(7.23)

where symbols with \( \sim \) is given in the rest frame of the ions, and \( \nu_e \) is the mean collision frequency between the electrons and the ions. There could easily be more forces included on the right hand side, such as gravity but even more importantly, the rest frame of the ions might not be inertial, so there could be inertial forces due to the non-linear movements of the ions. There could also be a collision term between the electrons and the neutrals, in case the plasma is not completely ionized, which would be almost identical to the collision term but now with a velocity that is the difference between the electrons and the neutrals. In this case we will concentrate on the ions and electrons. Because the electrons are so light compared to the ions we can assume that the electrons quickly reaches a state where there is a balance between the drag (the collisions with the ions) and the electromagnetic forces. That means that most of the time

\[
m_e \nu_e \tilde{u}' = -e \left( \tilde{E} + \tilde{u}' \times \tilde{B} \right)
\]  

(7.24)

If we look at a reasonably uniform medium the gyromotion of the electrons cancel out, in the sense that they produce no large scale currents, so when we are only interested in the large scale motions – much larger than the gyroradius we can also exclude the term that produces the gyro motions of the electrons in Eq. 7.24. That now leaves only

\[
m_e \nu_e \tilde{u}' = -e \tilde{E}
\]  

(7.25)

\[
\tilde{u}' = -\frac{e \tilde{E}}{m_e \nu_e}
\]  

(7.26)

so we have an expression for the velocity of the electrons relative to the ions (not including the gyromotions of the electrons). The current produced by these electrons are then simply

\[
\tilde{j} = -e n_e \tilde{u}' = \sigma \tilde{E}
\]  

(7.27)

which is Ohms law in the ions coordinate system and where

\[
\sigma = \frac{n_e e^2}{m_e \nu_e}
\]  

(7.28)
is the electric conductivity of the plasma. Now we only need to transfer this equation into a rest frame before we can use it as one of the MHD equations. Since the electric current depends on the difference between two velocities, then the difference between them will still be the same, i.e. the electric current remains the same in our laboratory rest frame:

\[ j = \tilde{j} \] (7.29)

Transferring fields between two frames of reference which have a relative velocity \( u \) gives

\[
\tilde{\mathbf{B}} = \mathbf{B} \quad (7.30) \\
\tilde{\mathbf{E}} = \mathbf{E} + u \times \mathbf{B} \quad (7.31)
\]

Inserting this back into the equation Eq. 7.27 we get

\[ j = \sigma (\mathbf{E} + u \times \mathbf{B}) \] (7.32)

Using this expression for \( j \) to eliminate the current in Eq. 7.20 and isolating the electric field \( \mathbf{E} \) gives

\[ \mathbf{E} = -u \times \mathbf{B} + \frac{1}{\mu_0 \sigma} \nabla \times \mathbf{B} \] (7.33)

and inserting that into the induction equation (Eq. 7.15) finally gives

\[ \frac{\partial \mathbf{B}}{\partial t} = \nabla \times (u \times \mathbf{B}) - \nabla \times (\eta \nabla \times \mathbf{B}) \] (7.34)

where we have introduced the resistive diffusion coefficient \( \eta = 1/\mu_0 \sigma \). That equation can be rewritten by using a vector identity:

\[ \nabla \times (\nabla \times \mathbf{A}) = \nabla (\nabla \cdot \mathbf{A}) - \nabla^2 \mathbf{A} \] (7.35)

and using this and assuming that the resistive diffusion coefficient is constant Eq. 7.34 can be rewritten into

\[ \frac{\partial \mathbf{B}}{\partial t} = \eta \nabla^2 \mathbf{B} + \nabla \times (u \times \mathbf{B}) \] (7.36)

This is the final version of the equation controlling the magnetic field evolution in MHD.
Exercise 7.7:
Do the steps from Eq. 7.32 to Eq. 7.36 as explained in the text

7.3.1 Physical interpretation

The equation for the evolution of the magnetic field (Eq. 7.36), can be understood reasonably simply. The first term on the right hand side of Eq. 7.36 simply a diffusion term, similar to a heat diffusion term. The physical interpretation is just that the magnetic field will try to smooth itself out over time. The second term on the right hand side of Eq. 7.36 is an advection term, but where only velocities perpendicular to the magnetic field is take into account. It can be seen by trying to write the terms in the $x$–component:

$$\frac{\partial B_x}{\partial t} = \eta \frac{\partial^2 B_x}{\partial x^2} + \left[ \frac{\partial}{\partial y} (u_x B_y - u_y B_x) - \frac{\partial}{\partial z} (u_z B_x - u_x B_z) \right]$$

(7.37)

If we imagine a magnetic field in the $x$ direction and a velocity in the $x$ direction, then it is clear from this equation that there is no change in any of the magnetic field components, since they all contain terms that are combinations of different combinations of $u$ and $B$. Let’s imagine a magnetic field in the $z$ direction with a velocity field perpendicular to it along the $x$ direction. Eq. 7.37 shows that only the last term gives a contribution

$$\frac{\partial B_x}{\partial t} = \frac{\partial}{\partial z} (u_x B_z)$$

(7.38)

which shows that if there is a velocity field which is not constant as a function of $z$, then there will be produced a field in the $x$ direction. That effect can better be visualized by using the concept of field lines. A field line is defined as a connected set of line segments that is described by

$$\frac{dx}{B_x} = \frac{dy}{B_y} = \frac{dz}{B_z}$$

(7.39)

or put more simply, a field line is a line that at all points along its length it is tangential to the direction of the magnetic field. It is important to realize that this is true at each time $t$ and that you can create a field line at each point in space (if the magnetic field strength is not identically zero). It means that it is not possible to “follow” a field line in time or space, but as we shall see later, it is possible to follow a specific amount of magnetic flux. The field line picture is only a tool we use to make it easier to visualize the field.
CHAPTER 7. MHD

Frozen in condition and ideal MHD

Ideal MHD is MHD where there is no electrical resistivity, or similarly no magnetic diffusivity. That means that the fluid is a perfect conductor and this picture is an approximation in any astronomical setting. In the solar corona, the particle density is only $10^{15}$ m$^{-3}$ (our atmosphere has roughly $10^{25}$ m$^{-3}$), but still the electrical conductivity is about the same as copper, so ideal MHD is a pretty good assumption in many cases. In order to get a more intuitive picture of the magnetic field, we use Gauss’ theorem which states that for a surface $S$ surrounding a volume $V$, then if $\mathbf{N}$ is a vector normal to the surface $S$ and that $d\mathbf{S} = \mathbf{N} dS$ then for a vector field $\mathbf{A}$,

$$\int_V \nabla \cdot \mathbf{A} dV = \int_S \mathbf{A} \cdot d\mathbf{S}$$

(7.40)

so using that on Eq. 7.16 shows that the total magnetic flux crossing any surface is zero:

$$\int_S d\mathbf{S} \cdot \mathbf{B} = 0$$

(7.41)

which is just showing that there are no magnetic charges in the universe. That also means that any field line going in through any closed surface $S$ must also come back out of that closed surface. It also means that the amount of magnetic flux through any surface enclosed by $C$ can be written:

$$\Phi = \int_C d\mathbf{S} \cdot \mathbf{B}$$

(7.42)

Now imagine a closed contour $C$ moving with the fluid for a time $dt$. The enclosed surface consisting of the contour $C$, $C'$ and the surface the contour has mapped out during the time $dt$ makes up a closed volume. If we call a small step along $C$, $d\mathbf{s}$, then after $dt$, $d\mathbf{s}$ has swept out an area $d\mathbf{s} \times \mathbf{u}$. The total flux through the whole surface of the created volume, is the sum of the flux passing through the original contour $C$, the final contour $C'$ and the area swept out by the line segments $d\mathbf{s} \times \mathbf{u}$,

$$\int_C d\mathbf{S} \cdot \mathbf{B}(t) - \int_{C'} d\mathbf{S}' \cdot \mathbf{B}(t + dt) - \int_C \mathbf{B}(t + dt) \cdot d\mathbf{s} \times \mathbf{u} dt = 0$$

(7.43)
at time \( t + dt \). So the difference in flux through the surface \( C \) and surface \( C' \) becomes

\[
\delta \Phi = \int_{C'} dS_C \cdot B(t + dt) - \int_C dS_C \cdot B(t) = \int_C dS_C \cdot [B(t + dt) - B(t)] - dt \oint \mathbf{B} \cdot d\mathbf{s} \times \mathbf{u}
\]

\[
= dt \left[ \int_C dS_C \cdot \frac{\partial \mathbf{B}}{\partial t} - \oint_C \mathbf{B} \cdot d\mathbf{s} \times \mathbf{u} \right]
\]

(7.44)

then assuming that there is no magnetic diffusion then

\[
\delta \Phi = dt \left[ \int_C dS_C \cdot \nabla \times (\mathbf{u} \times \mathbf{B}) - \oint_C \mathbf{B} \cdot d\mathbf{s} \times \mathbf{u} \right]
\]

(7.45)

and using Stokes theorem which says

\[
\int_C \nabla \times \mathbf{A} \cdot dS_C = \oint_C \mathbf{A} \cdot d\mathbf{s}
\]

(7.46)

then

\[
\delta \Phi = dt \oint (dS \cdot \mathbf{u} \times \mathbf{B} - \mathbf{B} \cdot dS \times \mathbf{u})
\]

(7.47)

\[
= dt \oint (\mathbf{B} \cdot dS \times \mathbf{u} - \mathbf{B} \cdot dS \times \mathbf{u})
\]

(7.48)

\[
= 0
\]

(7.49)

and finally using a vector identity to get from Eq. 7.47 to Eq. 7.48. The consequence is that magnetic flux through any contour that moves with the fluid is constant in time, no matter how \( \mathbf{B} \) and \( \mathbf{U} \) looks.

**Exercise 7.8:**
Show that the vector identity used to get to Eq. 7.48 is true by writing out the three components of the first and second term in Eq. 7.47

Imagine now tubes of flux that move with the fluid, then if the tubes moved relative to the fluid, there would be tubes experiencing changes in flux, which cannot happen. So the flux tubes have to move with the fluid. That condition is called the “frozen in” condition, because the fluid and the flux move together.
Resistive diffusion

Resistive diffusion is usually a small effect but it is a crucial effect in the solar atmosphere, where resistive diffusion is the effect that produces the giant solar flares and coronal mass ejections that heats the coronal plasma to tens of millions of degrees and can eject huge amounts of fast moving plasma that can disrupts satellite communication and induce large currents in high voltage power lines. The terms on the right hand side of Eq. 7.36 are in competition to control the evolution of the magnetic field. They have a magnitude of $\eta B/l^2$ and $uB/l$ respectively, where $B$ is the magnitude of the magnetic field, and $l$ is the smallest characteristic scale of the magnetic field and velocity field. The ratio of these numbers is called the magnetic Reynolds number

$$R_m = \frac{uB}{l} \frac{l^2}{\eta B} = \frac{ul}{\eta}$$  \hspace{1cm} (7.50)

and when $R_m$ is very large compared to one, then the convective term is much more important than the resistive diffusion term, so the field is carried with the fluid. When $R_m$ is small then the diffusion of the field is much stronger than the advection term, so the magnetic field will diffuse out of the fluid faster than it can be concentrated by the field. In almost all astrophysical circumstances, the resistive diffusion is very small.

**Exercise 7.9:**

Calculate the magnetic Reynolds number for the following astrophysical settings:

- The solar photosphere: The granular pattern has a typical size of 1Mm, velocity of 1 km s$^{-1}$ and $\eta \sim 10^5$ m$^2$ s$^{-1}$
- The solar wind: The typical size of structures are roughly 1 earth radius, velocities are typically 400 km s$^{-1}$ and the resistive diffusion coefficient is roughly 100 m$^2$ s$^{-1}$.
- The galactic disc: The typical size is 100 pc, the typical velocity is 10 km s$^{-1}$ and the resistive diffusion coefficient is $10^5$ m$^2$ s$^{-1}$.

Is should be noted that as long as the collision frequency between electrons and ions is higher than the electron Larmor frequency, the electron drift is dominated by collisions, and then the resistive diffusion coefficient can be written as

$$\eta = 10^9 \ T^{-\frac{3}{2}} \ m^2 \ s^{-1}$$  \hspace{1cm} (7.51)
but it is important to notice that this is only true (and all of the previous discussion using the resistive diffusion coefficient), when the majority of the particles are electrically charged. If that is not the case, every electrically charged particle will have to “drag” the neutrals with them through collisions which will affect both the diffusion of the magnetic field, and the whole foundation of MHD. If there is a significant portion of the particles that are neutral, MHD can be changed by including a number of terms that treat the interaction between the neutrals and the electrically charged particles, but treating those terms here would be going too far. An amount of neutral particles large enough to affect the dynamics are possibly present in the upper solar photosphere, but that is a topic of cutting edge research at the moment.

**Exercise 7.10:**
The magnetic field in interstellar clouds have a typical size of $10^{-9}$ T, and the density of $10^3$ m$^{-3}$. Assume that the magnetic field is passively advected by the gas as it coalesces and becomes the sun (use only average values for the present sun), and calculate the magnetic field strength that the sun should have by using the frozen-in condition where the amount of flux passing through a surface is constant, when the surface moves with the fluid.

### 7.4 The magnetic field and its forces

The magnetic field threads plasma over large distances. The forces it transmits to the plasma can therefore be a consequence of plasma movements at large distances. That is very different from hydrodynamics, where the forces experienced by a fluid parcel is only dependent on the neighboring fluid parcels. If we look at the force experienced by a charged particle in its own frame of reference, then it is simply

$$f' = qE'$$  \hfill (7.52)

where $f$ and $E$ is the force experienced by the particle with charge $q$ and the electric field respectively. Both of these are here in the reference frame of the particle, so have been denoted with a mark. Transferring this to an inertial frame of reference, gives

$$f = q(E + u \times B)$$  \hfill (7.53)

where the particle moves with the velocity $u$ in the inertial frame of reference. A plasma by definition contains a large number of charge carriers in a unit
volume, so if the overall charge of the volume is \( q_e \), then the force per unit volume is

\[
\mathbf{F} = q_e \mathbf{E} + j \times \mathbf{B}
\]  

(7.54)

since the charge times the velocity is just the electric current. We have already seen that the electric field is much weaker than the magnetic field, so the force exerted by the electric field is therefore much smaller than the force exerted by the magnetic field, so that with the help of Eq. 7.20 we can write Eq. 7.54 to

\[
\mathbf{F} = 0 + \frac{1}{\mu_0} (\nabla \times \mathbf{B}) \times \mathbf{B}
\]  

(7.55)

which finally can be rewritten using the vector identity for two vector fields \( \mathbf{A} \) and \( \mathbf{B} \)

\[
\nabla (\mathbf{A} \cdot \mathbf{B}) = (\mathbf{B} \cdot \nabla) \mathbf{A} + (\mathbf{A} \cdot \nabla) \mathbf{B} + \mathbf{B} \times (\nabla \times \mathbf{A}) + \mathbf{A} \times (\nabla \times \mathbf{B})
\]  

(7.56)

into

\[
\mathbf{F} = -\frac{1}{\mu_0} \left[ \frac{1}{2} \nabla B^2 - (\mathbf{B} \cdot \nabla) \mathbf{B} \right]
\]  

(7.57)

**Exercise 7.11:**

Use Eq. 7.56 to show that Eq. 7.55 can be transformed into Eq. 7.57

The force is a regular body-force, so can be plugged directly into the momentum equation. The two terms have very different properties and both are similar to two reasonably well known forces. We can immediately see that magnetic fields that satisfy \( \nabla \times \mathbf{B} = 0 \) produces no force on the plasma. This type of field is called a potential field, because it can be created as the gradient of a scalar field but it is a special case of the more general force free fields. Force free fields is a large family of fields that do not produce any force on the plasma and they all satisfy \( \nabla \times \mathbf{B} = \alpha(r)\mathbf{B} \), where \( \alpha(r) \) is a scalar function. Fields where \( \alpha \) is a constant are called linear force free, while fields where \( \alpha(r) \) is non constant are called non linear force free. Such fields have a complete balance between the two terms in Eq. 7.57. For fields that are not force free the two terms do are not in balance, and the plasma will feel a force from the magnetic field.

**Exercise 7.12:**

Show that magnetic fields obeying \( \nabla \times \mathbf{B} = 0 \) and \( \nabla \times \mathbf{B} = \alpha(x)\mathbf{B} \) produces no Lorentz force
The magnetic pressure

The first term on the right hand side of Eq. 7.57 is just the gradient of scalar field so completely identical to the gas pressure, where now the pressure is no longer delivered by the thermal motions of the particles, but by the magnetic fields influence over the particles motions. The force works completely analogous to the thermal pressure, where the pressure for an ideal gas is \( P_g = N k T \), then the magnetic pressure is just \( P_m = B^2 / 2 \mu_0 \).

The magnetic tension

The second term is somewhat more complicated. Let’s look at the \( x \)-component of the force

\[
\left( B_x \frac{\partial}{\partial x} + B_y \frac{\partial}{\partial y} + B_z \frac{\partial}{\partial z} \right) B_x
\]  

(7.58)

That is somewhat complicated to get a physical understanding from, but basically it says that you need a gradient of one of the components of the magnetic field, but at the same time you need the field to also be along that gradient. It basically means that if there is a curvature of the field, then there will be a force towards the centre of the curvature. To exemplify it in a slightly easier way, then imagine a magnetic field curving around the \( z \)-axis of a cylindrical coordinate system forming a magnetic cylinder. In the cylindrical coordinate system, the magnetic field would have the following components

\[
B_\phi = B_0.
\]  

(7.59)

\[
B_r = 0.
\]  

(7.60)

\[
B_z = 0.
\]  

(7.61)

and the magnetic field would have a magnitude \( B_0 \) everywhere. This field clearly obeys \( \nabla \cdot \mathbf{B} = 0 \) and we can now calculate the two components of the Lorentz force: The magnetic pressure force gives no contribution as the field is constant everywhere. The second term has the following structure in cylindrical coordinates:

\[
F_r = \frac{1}{\mu_0} \left[ B_r \frac{\partial B_r}{\partial r} + \frac{B_\phi}{r} \frac{\partial B_r}{\partial \phi} + B_z \frac{\partial B_r}{\partial z} - \frac{B_\phi^2}{r} \right] = - \frac{B_\phi^2}{\mu_0 r}
\]  

(7.62)

\[
F_\phi = \frac{1}{\mu_0} \left[ B_r \frac{\partial B_\phi}{\partial r} + \frac{B_\phi}{r} \frac{\partial B_\phi}{\partial \phi} + B_z \frac{\partial B_\phi}{\partial z} + \frac{B_\phi B_r}{r} \right] = 0
\]  

(7.63)

\[
F_z = \frac{1}{\mu_0} \left[ B_r \frac{\partial B_z}{\partial r} + \frac{B_\phi}{r} \frac{\partial B_z}{\partial \phi} + B_z \frac{\partial B_z}{\partial z} \right] = 0
\]  

(7.64)
which gives only a contribution directed towards the centre of the coordinate system. The second term in the Lorentz force is therefore often called a tension force, because it works against any curvature of the field and will try to straighten the field out. The smaller the radius of the curvature, or the sharper the field has been bent, the greater the force. Here the force decreases with \( r \) because the field is closer and closer to be straight for increasing \( r \).

**Exercise 7.13:**
Assume that a cylindrical magnetic flux tube is embedded in a plasma with \( P = 10^8 \) Pa. Assume that the field is along the \( z \)-axis in a cylindrical coordinate system, that the flux tube has a radius of 1 Mm and that there is no plasma inside the flux tube. What does the magnetic field need to be in order for the system to be in equilibrium?

Let’s look at two different twisted flux ropes. None of these are very realistic because it turns out that the balance of the magnetic pressure force and the magnetic tension force is an ill posed problem.

The force balance is simple that the two forces must balance each other, and as we have just seen, a curved magnetic field gives a simple expression for the tension force, so we imagine now a magnetic field that curves around the \( z \)-axis of a cylindrical coordinate system. Also assume that there is no gradients in the \( \phi \)-direction, and that there are no other important forces present. In that case we just have the balance of the two forces:

\[
\frac{B_\phi}{\mu_0 r} = \frac{1}{2\mu_0} \frac{\partial B^2}{\partial r}
\]  

(7.65)

The first flux rope has a simple functional form of the rotational part of the magnetic field: \( B_\phi = B_0 r \), where \( B_0 \) is a constant. This field is of course not realistic as the field strength would grow to infinite values. If we insert that into Eq. 7.65, we get

\[
\frac{B_0^2 r^2}{\mu_0 r} = \frac{1}{2\mu_0} \left[ \frac{\partial B_\phi^2}{\partial r} + \frac{\partial B_z^2}{\partial r} \right]
\]

\[
2B_0^2 r = B_0^2 \frac{\partial r^2}{\partial r} + \frac{\partial B_z^2}{\partial r}
\]

\[
\frac{\partial B_z^2}{\partial r} = 0
\]

\[
B_z = B_{z,0}
\]  

(7.66)
7.5 FINAL MHD EQUATIONS

where $B_{z,0}$ is an arbitrary constant. This is a very simple solution to the force balance equation and as mentioned not realistic, since the field strength would grow to infinity.

The second example of a flux rope is a bit more complicated. Here we again assume the same symmetry, but here

$$B_\phi = B_0 r \cos (r) \quad (7.67)$$

where $B_0$ is a constant. We also assume that this equation only holds for $0 \leq r \leq \pi / 2$. For values of $r > \pi / 2$ we assume that there is a gas pressure which has the same value as the magnetic pressure at $r = \pi / 2$. We have already calculated the force from curved magnetic field in Eq.7.62, so if we balance that against the other magnetic term in the force balance we just get

$$\frac{B_\phi^2}{\mu_0 r} - \frac{1}{2\mu_0} \frac{\partial (B_z^2 + B_\phi^2 + B_z^2)}{\partial r} = 0 \quad (7.68)$$

where we again assume that there are no other forces at play, or that they balance each other perfectly. Inserting Eq.7.67 gives

$$B_0^2 r^2 \cos (r)^2 \quad (7.69)$$

$$\frac{\partial B_z^2}{\partial r} = \frac{1}{2} \frac{\partial}{\partial r} \left( B_z^2 + B_0^2 r^2 \cos (r)^2 \right)$$

$$B_z^2 = \frac{2B_0^2 r \cos (r)^2 - B_0^2 r^2 \cos (r)^2}{2}$$

$$\frac{\partial B_z}{\partial t} = \frac{\eta \nabla^2 \mathbf{B} + \nabla \times (\mathbf{u} \times \mathbf{B})}{\mu_0} \quad (7.72)$$

where $\mathcal{E}$ is the internal energy of the gas, $G$ is the gravitational force and the Lorentz force has been added to the momentum equation. The internal
energy depends on a number of things. It depends on the velocity through advection, the magnetic field and the resistive diffusion creates heat and finally the viscous stress also provides heat. The final equation which we have also used in the HD chapter is the equation of state which is the final equation needed to close this equation set.

7.6 MHD waves

As in HD, MHD has its own types of waves, driven by the restoring force of the magnetic field. As the magnetic field has both the tension force and the magnetic pressure that can act as a restoring force as well the gas pressure, there is a number of different wave modes that can be exited in MHD, while HD only has one: The sound wave. To get to the equations for MHD waves, we need a few preparations. As we did in HD, we now assume that we have a medium in equilibrium, and that the waves are small perturbations on top of the equilibrium values, giving

\[
\begin{align*}
\rho &= \rho_0 + \rho' \\
P &= P_0 + P' \\
\mathbf{u} &= \mathbf{u}_0 + \mathbf{u}' \\
\mathbf{B} &= \mathbf{B}_0 + \mathbf{B}'
\end{align*}
\]

where the 0 subscripts denote the equilibrium values and the marked variables are the small perturbations. We further assume that the medium is homogeneous and that it does not move, which means that there are no spatial or time gradients of the equilibrium values and that \( \mathbf{u}_0 = 0 \). We make use of the equations for small perturbations in density at constant entropy (Eq. 6.29) again

\[
\frac{P'}{\rho'} = \left( \frac{\partial P}{\partial \rho_0} \right)_s = c_s^2
\]  

(7.73)

We now describe the small perturbations as wavelike, so that for instance

\[
\mathbf{u}' = u^* \exp(-i (\omega t - \mathbf{k} \cdot \mathbf{x}))
\]  

(7.74)

where \( u^* \) is just a scalar and \( \mathbf{k} \) is the wave vector which is the direction of the wave propagation. Now we are ready to rewrite the mass conservation equation as

\[
\begin{align*}
\frac{\partial \rho_0 + \rho'}{\partial t} &= -\nabla \cdot \left[ \left( \rho_0 + \rho' \right) \mathbf{u}' \right] \\
\frac{\partial \rho'}{\partial t} &= -\nabla \cdot \left( \rho_0 \mathbf{u}' + \rho' \mathbf{u}' \right)
\end{align*}
\]  

(7.75)  

(7.76)
and again as before we now ignore terms where two very small terms are multiplied, as in this case \( \rho' \mathbf{u}' \). Then finally the equation of mass conservation becomes

\[
\frac{\partial \rho'}{\partial t} = -\rho_0 \nabla \cdot \mathbf{u}'
\]

\[-i\omega \rho' = -\rho_0 (i\mathbf{k}) \cdot \mathbf{u}'
\]

\[
\rho' = \frac{\rho_0}{\omega} \mathbf{k} \cdot \mathbf{u}' = \frac{P'}{c_s^2}
\]

\[
P' = \frac{c_s^2 \rho_0}{\omega} \mathbf{k} \cdot \mathbf{u}'
\]  \hspace{1cm} (7.77)

(7.78)

where we have inserted the wavedescription of the perturbations and used Eq. 7.73.

We now continue to treat the equation for the magnetic field the same way and assuming that the magnetic diffusivity \( \eta \) is so small that we can ignore it here.

\[
\frac{\partial \mathbf{B}}{\partial t} = -\nabla \times (\mathbf{u} \times \mathbf{B})
\]

\[
\frac{\partial \mathbf{B}'}{\partial t} = -\nabla \times [\mathbf{u}' \times (\mathbf{B}_0 + \mathbf{B}')] 
\]

\[
\frac{\partial \mathbf{B}'}{\partial t} = -\nabla \times (\mathbf{u}' \times \mathbf{B}_0) 
\]

\[-i\omega \mathbf{B}' = -i\mathbf{k} \times (\mathbf{u}' \times \mathbf{B}_0) 
\]

\[
\mathbf{B}' = \frac{1}{\omega} \mathbf{k} \times (\mathbf{u}' \times \mathbf{B}_0) 
\]  \hspace{1cm} (7.79)

and finally we can now do the same with the momentum equation, where again we assume the dissipative effects are very small and can be ignored.
which removes the viscous stress tensor term:

\[
\frac{\partial \rho u}{\partial t} = -\nabla P - \frac{1}{\mu_0} (\nabla \times \mathbf{B}) \times \mathbf{B} \\
\frac{\partial \rho u'}{\partial t} = -\nabla P' - \frac{1}{\mu_0} (\nabla \times \mathbf{B}') \times \mathbf{B}_0 \\
\rho_0 (-i\omega) \mathbf{u}' = -i k P' - \frac{1}{\mu_0} (i k \times \mathbf{B}') \times \mathbf{B}_0 \\
-\omega^2 \rho_0 \mathbf{u}' = -i k \frac{c_s^2 \rho_0}{\omega} (\kappa \cdot \mathbf{u}') - \frac{i}{\mu_0} (k \times \mathbf{B} \times \mathbf{B}_0) \\
\frac{\omega^2}{k^2} \mathbf{u}' = \frac{c_s^2}{k^2} (\kappa \cdot \mathbf{u}') \kappa + \frac{1}{\rho_0 \mu_0 k^2} \left[ k \times \left( k \times \left[ \mathbf{u}' \times \mathbf{B}_0 \right] \right) \right] \times \mathbf{B}_0 \\
\frac{\omega^2}{k^2} \mathbf{u}' = c_A^2 \left( \kappa \cdot \mathbf{u}' \right) \hat{k} + \frac{B_0^2}{\rho_0 \mu_0} \left[ k \times \left( \hat{k} \times \left[ \mathbf{u}' \times \hat{\mathbf{B}}_0 \right] \right) \right] \times \hat{\mathbf{B}}_0 \\
\frac{\omega^2}{k^2} \mathbf{u}' = c_A^2 \left( \kappa \cdot \mathbf{u}' \right) \hat{k} + c_A^2 \left[ k \times \left( \hat{k} \times \left[ \mathbf{u}' \times \hat{\mathbf{B}}_0 \right] \right) \right] \times \hat{\mathbf{B}}_0 
\] (7.80)

where we have used both Eq. 7.78, Eq. 7.79 and defined the Alfvén speed
\[ c_A = \frac{B_0}{\sqrt{\rho_0 \mu_0}}. \] Eq. 7.80 is clearly a wave equation with two components. The terms all have the same size, and if we ignore the directional information in the unit vectors on the right hand side the magnitude of the wave velocity can be found from:

\[
\frac{\omega^2}{k^2} |\mathbf{u}'| = x_1 c_s^2 |\mathbf{u}'| + x_2 c_A^2 |\mathbf{u}'| 
\] (7.81)

where \( x_1 \) and \( x_2 \) are functions of the directional vector expressions in Eq. 7.80 and have values between \(-1\) and \(+1\). That means that the wave speed is within the range of values given by

\[
c_w^2 = x_1 c_s^2 + x_2 c_A^2 
\] (7.82)

which has two solutions, so that the wave speed is between \( c_A - c_s \leq c_w \leq c_A + c_s \) (here assuming that \( c_A > c_s \)).

There are several types of waves that comes out of this wave equation. If the velocities \( \mathbf{u}' \) is along the magnetic field, then the second term of Eq. 7.80 is zero, and we only have a wave propagating if the wave vector is not perpendicular to \( \mathbf{u}' \), and the speed will then be \( c_s \sqrt{\kappa \cdot \mathbf{u}'} \). This type of wave moves primarily in the direction of the equilibrium magnetic field \( \mathbf{B}_0 \) and it has a velocity \( c_s \). From Eq. 7.79 we see that there is no effect on the
magnetic field, and from Eq. 7.78 that the wave is compressing the gas. It is important to notice that this wave can move slightly across the field, but the velocity perturbation is always along the magnetic field. If it is not, the wave gets a contribution from the second term in Eq. 7.80. This wave is a very special solution of Eq. 7.80.

There are another special case, which is the Alfvén wave. The solution comes about if $\mathbf{k} \cdot \mathbf{u}' = 0$, in other words the direction of the wave is perpendicular to the plasma movements. From Eq. 7.78 we see that the wave does not compress the gas, and from Eq. 7.79 we see that the magnetic field is perturbed, so this is a wave that is only a wave in the magnetic field. It is a wave motion of the magnetic field lines, which does makes the gas move back and forth perpendicular to the equilibrium magnetic field direction. It moves with the velocity $c_A$ which in the sun is often much higher than the sound speed.

There are two types of waves that are combinations of the Alfvén wave and the sound wave. These are called the slow and the fast magnetosonic wave. The fast magnetosonic wave is a wave which is able to bend the magnetic field lines, as well as compress the gas so that both the gas pressure and the magnetic field is able to work as restoring forces in the wave propagation. The fast magnetosonic wave degenerates to an Alfvén wave when the wave moves along the magnetic field direction, while when it moves perpendicular to the magnetic field, it is able to move faster than both the sound speed and the Alfvén speed because the two restoring forces work in phase, giving it a wavespeed that is $c_s + c_A$. The slow magnetosonic wave is a wave where the two restoring forces are out of phase and the slow mode can only move along the magnetic field. For the slow mode, the magnetic field is also bent as in the Alfvén wave, but the pressure perturbations are out of phase, and the velocity can then at most become $c_A - c_s$ (assuming that $c_A > c_s$).

Appendix C

Modelling energy production

This project involves extracting the energy production at the center of a star, given a temperature and density. The project involves information contained in Chap. 1–4.

Goal

In this project you are to write a function or subroutine that accepts a temperature and a density as input, and then calculates the amount of energy produced by the PP fusion chains.

Requirements

This function/subroutine is to be part of your later model of a star, and you can use any programming language you like, as long as it can be run on a standard non MS-Windows computer and if a software license is needed, it must be available at the Institute of theoretical astrophysics.

Assumptions

- You can assume that you know the mass fractions of each atomic species, and that these are independent of radius:
\[ X = 0.7 \]
\[ Y_3 = 10^{-10} \]
\[ Y = 0.29 \]
\[ Z = 0.01 \]
\[ Z_{^7\text{Li}} = 10^{-13} \]
\[ Z_{^7\text{Be}} = 10^{-13} \]

- When you calculate the electron density you can assume that the ”metals” \((Z)\) contribute the usual number of electrons and that all other elements are fully ionized.

- You only need to include the processes that make up the PPI and PPII reaction chains (PPIII and the CNO cycle do not contribute in our model).

- You may combine the first two steps (common to all branches) as a single step with the same reaction rate: We assume that the \(^7\text{D}\) produced is immediately consumed by the next step to produce \(^3\text{He}\).

- We will not consider changes over time to the mass fractions of \(^1\text{H}\) and \(^4\text{He}\) in this project (we are looking at a snapshot of a star at a particular moment in time).

**Tasks**

- Before you begin coding, identify the units (in the SI system) of the following variables: \(T_\beta, \lambda_{ik}, r_{ik}, Q_{ik}\) and \(\varepsilon\). This will make your task easier once you start coding.

  - For some of these, you may want to use “number of reactions” (or just “reactions”) as one of the units involved. In reality, this will be just a unitless number, but it will make it much clearer what the variables stand for.

  - In Table 3.1, Avogadro’s constant is considered to be unitless. If you want to express \(N_A\) in moles, then you may consider the reaction rates in the table to be given in units of \(\text{cm}^3\text{s}^{-1}\text{mol}^{-1}\).
APPENDIX C. MODELLING ENERGY PRODUCTION

- Using the density and temperature of the solar core (see App. B), write a function/subroutine for calculating the energy production (in SI units), including all steps in the PPI and PPII chains.

  - You should include the upper limit of the $^7$Be electron capture at this point and test that it works. It is not needed for such high temperatures as considered here (the sanity check), but it will be used later.

- Once this is done, adjust your function/subroutine so that no step consumes more of an element than the previous step(s) are able to produce. (You do not need to solve the full equations presented in Chap. 3.5 - a simple if-test will suffice.)

Results

You do not need to write a report on these results, but as a sanity test, you should get the following results, when using the density and temperature of the solar core (see App. B):

\[
\begin{align*}
  r_{pp} (Q_{pp} + Q_{Dp}) \rho &= 4.04 \cdot 10^2 \text{ J m}^{-3} \text{ s}^{-1} \\
r_{33} Q_{33} \rho &= 1.94 \cdot 10^{-6} \text{ J m}^{-3} \text{ s}^{-1} \\
r_{34} Q_{34} \rho &= 4.88 \cdot 10^{-5} \text{ J m}^{-3} \text{ s}^{-1} \\
r_{7e} Q_{7e} \rho &= 1.53 \cdot 10^{-6} \text{ J m}^{-3} \text{ s}^{-1} \\
r_{71} Q_{71} \rho &= 5.32 \cdot 10^{-4} \text{ J m}^{-3} \text{ s}^{-1}
\end{align*}
\]
Appendix D

Modelling a stellar core

Term project 1

The first term project involves modeling the central parts of the sun by writing a computer program to solve the governing equations. The project involves information contained in Chap. 1–5.2.1.

Solve the equations governing the internal structure of the radiative core of the Sun. You are free to use the programming language you prefer, and the numerical method you prefer. The equations you are to solve are the following:

\[
\begin{align*}
\frac{dr}{dm} &= \frac{1}{4\pi r^2 \rho} \\
\frac{dP}{dm} &= -\frac{Gm}{4\pi r^4} \\
\frac{dL}{dm} &= \varepsilon \\
P &= P_G + P_{rad} \\
\frac{dT}{dm} &= -\frac{3\kappa L}{256\pi^2 \sigma r^4 T^3}
\end{align*}
\]

The first differential equation comes from the expression for mass within a radius \(m(r)\). The second equation comes from the assumption of hydrostatic equilibrium. The third comes from the definitions of \(L\) and \(\varepsilon\). The final differential equation is a solution to the radiative diffusion equation (with no conduction or convection).

\(^{1}\)This term project has been improved by Odd Petter Sand (2015)
APPENDIX D. MODELLING A STELLAR CORE

The reason $m$ is used as the independent variable is that the set of equations is more stable than it would be if we used $r$ (but we will still use the $r$ results to make plots once we are done with solving the equations).

You will notice that you have 7 unknowns ($r, \rho, P, L, P_G, P_{rad}, T$) but only 5 equations (we assume $m, \kappa$ and $\varepsilon$ to be known, since we choose $m$, pick $\kappa$ from a table (see Tasks) and can adapt the calculations from App. C to get $\varepsilon$). Thus, you need two more equations. You can assume an ideal gas to get an equation of state, and you’ll need an equation for the radiation pressure as well. All the symbols have the standard meaning.

NOTE: There is no equation for $\frac{\partial \rho}{\partial m}$; this is by design. Solving such an equation in your program will lead to unphysical results.

Assumptions

- All the assumptions from App. C.
- Ideal gas.

Goals

Your final code should produce a star that:

- Has $L, m, r$ all going to 0 or at least within 5% of $L_0, M_0, R_0$, respectively.
- Has a core ($L < 0.995$) reaching out to at least 10% of $R_0$.

Initial parameters

As a starting point, we input the actual values at the bottom of the solar convection zone (except $P$, which will differ because we are assuming an ideal gas, and $M$, which is simply the mass of the entire Sun). Note that $\bar{\rho}_\odot$ is the average density of the Sun: $\bar{\rho}_\odot = 1.408 \cdot 10^3$ kg m$^{-3}$
\[ L_0 = 1.0 \cdot L_\odot \]
\[ R_0 = 0.72 \cdot R_\odot \]
\[ M_0 = 0.8 \cdot M_\odot \]
\[ \rho_0 = 5.1 \rho_\odot \]
\[ T_0 = 5.7 \cdot 10^6 \text{K} \]
\[ X = 0.7 \]
\[ Y = 0.29 \]
\[ Y_{\beta} = 10^{-10} \]
\[ Z = 0.01 \]
\[ Z_{\text{Li}} = 10^{-13} \]
\[ Z_{\text{Be}} = 10^{-13} \]

For the final task (see Tasks), it should be possible to find a solution with no parameter changing more than a factor of 5 (i.e. from \( \frac{1}{5} \) to 5 times the value in the table). Yes, that means you can indeed increase \( R_0 \) so it is larger than the radius of the Sun.

You may not change the mass fractions \( X, Y, Z \), the luminosity \( L_0 \) and the mass \( M_0 \), only the other parameters.

Tasks

- Create a method that reads the file the file \texttt{opacity.txt}\(^2\) (found on the course webpage) and takes \( T \) and \( \rho \) (in SI units) as input and returns \( \kappa \) (in SI units). You will need to use linear 2D interpolation for the common case where the input value is not exactly found in the table. Your code should also be able to extrapolate if you outside the bounds of the table (though you may want to have your program output a warning when you do so). Test your methods against the first sanity check below and see that you are able to reproduce the results shown there. The structure of the file is as follows:

  - The top row is \( \log_{10}(R) \), where \( R \equiv \frac{\rho}{(T T_{\odot})^\alpha} \) and \( \rho \) is given in cgs units (\( \frac{g}{\text{cm}^3} \)).

APPENDIX D. MODELLING A STELLAR CORE

- The first column is $\log_{10}(T)$, with $T$ given in K as usual.
- The rest of the table is $\log_{10}(\kappa)$, again in cgs units ($\frac{cm^2}{g}$).

- Implement methods to calculate $\rho(P, T)$ and $P(\rho, T)$. (Why not also for $T$?)

- You are now ready to begin on the main body of the program: Solving the four partial differential equations. You can choose which ever numerical method you prefer (Euler, Runge-Kutta, Simpson’s method, for instance). It is extremely helpful to print the parameters to screen for every 50 steps or so.

- Have your program output final values of the parameters.

- Implement dynamic step size (see the file variablesteplength.pdf on the course web page for details). Make sure you can turn dynamic step size on and off as needed.

- See “Sanity checks” and “Report” below and have your program create the plots you will need.

Sanity checks

Your first sanity check is to test your functions $\rho(P, T)$ and $P(\rho, T)$. Check that $\rho(P(\rho_0, T_0), T_0) = \rho_0$ and similarly for $P(\ldots)$ so you’re confident that your equation of state functions work both ways.

Interpolation of opacity values should give these results (or something very close to them):

<table>

</table>
If your code works correctly, you should get (approximately) the following plots using the given initial parameters:

Some notes on debugging your code

For some of you, this project represents a significant step up in scope and complexity from what you are used to in programming projects. As such, here are a few pointers for the all but inevitable situation that something is wrong with your code, but you don’t know what. **Read this before you start writing your code**, and keep it in mind throughout the project:

- Don’t write the entire program all at once. Take one task at a time and use the sanity checks whenever available. When you’re convinced it works as it should, you can move on to the next task.

- Repeat the process above for tasks you’ve already completed if you can’t find a bug. It’s possible you changed something so that your old code no longer passes the sanity checks.

- Only fix one bug at a time.
• If you get bugs that crash your program (giving an error message or doesn’t compile\(^3\)), read carefully what the error message says. If you don’t know what it means, copy the error message into a search engine. There’s almost always someone else out there that has encountered the same thing before you.

• Start from the top of your code, and fix those errors first. A later error might have been caused by the earlier one - make sure that this is not the case before moving on to the next bug.

• Print out all your variables for every step if you can’t locate the error, and see if anything’s off. In Python, use `print` statements to output the values of variables you want to check on. You may use `input()` to pause your program so you can look at the printouts before continuing. If not using Python, you can look up how to do this in your language of choice. (If you have access to a proper debugger that can set break points (i.e. pause the program, so you can execute one line of code at the time) and watches (watch how the value of a variable changes for each step), that’s even better, but entirely optional.)

• Common causes of bugs that are notoriously hard to track down:
  
  – Long division. Every time you’re working with real numbers, make sure to use real literals like 1.0. and 2.0 - do not use integer literals like 1 and 2 - these are dangerous. Look at the difference between `print exp(1/2)` and `print exp(1.0/2.0)` and recoil in horror as you contemplate what this would do to your results.

  – Avoid variables with the same name at all costs. In Python, you cannot flag a variable as constant (as in “forbidden to overwrite once declared”), so it is possible to overwrite a constant if you’re not careful. Blame the Python creators for this unfortunate possibility. Example: Defining the speed of light \(c = 2.998 \cdot 10^8\) and then later using an integer counter named \(c\) is a typical example of a bug which can be very difficult to track down: “Wait, how did I end up with a light speed of zero?”

  – (Add your own and suggest them to the teacher for the benefit of future students.)

\(^3\)Only applies if you’re not using Python. Some other languages require you to compile your program before running it.
The report

You are required to write a report in this exercise - writing down the method you use and in which order you solve the equations, etc. You also need to include what problems and what you have found out while solving this exercise, this includes both numerical problems, resolution problems and problems with the physics. The report needs to be well structured and understandable. The way your report is written does impact the number of points you will get for this project.

The report has to include a printout of the code as well as a file with your code so that it can be run on a non-MS Windows machine and any licenses required must be available at the Institute of Theoretical Astrophysics. Your code will have to be written so that not only yourself can read it, and it will have to be commented, meaning that when defining a variable or constant, it has to be explained as well as when calculating something that will have to explained as well. The code should be structured logically so that it is easily understandable. This is a very important point - if I do not understand what happens in the code, it will mean a serious deduction in the number of points you will get - even if you successfully solve it!

There will be no extensions to the deadline, except in case of documented medical circumstances. If you cannot solve it, write the report anyway, explaining your problems and what you tried in order to solve them.

Your report should contain the following:

• Describe how you calculate the average molecular weight, $\mu$.

• Plot $r$ as a function of $m$ with dynamic step size turned off for significantly different step sizes $\partial m$. Once you have sufficient data, comment on the effects of changing the step size.

• By running several experiments, you should report what happens when you

  – change the value of $R_0$ (keeping all other initial parameters unchanged).
  – change the value of $T_0$ (keeping all other initial parameters unchanged).
  – Change the value of $\rho_0$ (keeping all other initial parameters unchanged).
  – change the value of $P_0$ (keeping all other initial parameters unchanged).
You need to run several experiments for each of these – not just two or three.

- Explain why the changes happen.
- Does changing some of the parameters produce very similar effects?
- Are there cases where you may compensate for changing one parameter by changing another (and if so, in which direction should you change them)?

There is no limit on how many words you should use, but make it as brief as you can without leaving out anything important. A bulleted list is fine for this purpose if that is what you prefer.

- Finally, try to create a model where both the radius and the luminosity becomes zero when the mass becomes zero (See “Goals”). You are here free to change any of the three initial parameters we changed in the previous task ($\rho_0$, $P_0$, $T_0$ and $R_0$).

  - A good starting point is trying to make $m$ and $r$ go to 0 (+/- 5% of the initial value) at the same time, using what you’ve learned so far.
  - Pay special attention to what happens to $\rho$ as a consequence of how $r$ behaves. Study them and see what happens. Comment on the results.
  - It’s easier to get convergence to 0 if your core is very small ($L$ drops very fast). In other words, there is a tradeoff to be made here: By having one of your variables not go all the way to 0, you can get a more realistic core.
  - Extrapolating in the opacity table is most likely inevitable. Don’t worry about this if it happens.

- For your best model, plot the values of $T$, $L$, $\varepsilon$, $\rho$, $P$ and $m$, all as a function of the radius $r$ (to get an idea what a cross section of your star actually looks like). Use a logarithmic axis for $\varepsilon$, $\rho$ and $P$. Explain your choice of parameters by using these plots.
Appendix E

Modelling a star

Term project 2

The third term project now involves using Chap. 5 to include convection in your model of a star. In the first term project you modelled the sun from its core to the edge if its radiative zone. Now you can include the rest of the sun by including energy transport through convection.

Assumptions

- All the assumptions from project 1 still apply.
- There is no heat conduction in the star, only radiation and convection.

Goals

Your final code should produce a star that:

- Has $L$, $m$, $r$ all going to 0 or at least within 5% of $L_0$, $M_0$, $R_0$, respectively.
- Has a core ($L < 0.995$) reaching out to at least 10% of $R_0$.
- Has a continuous convection zone (is convectively unstable) near the surface of the star. The width of this convection zone should be at least 15% of $R_0$. (A small radiation zone at the edge is acceptable. So is a second convection zone closer to the center, but the convective flux should be small here compared to the “main” convection zone near the surface).

---

1This term project has been improved by Odd Petter Sand (2015)
• Has PPI dominating at low temperatures and PPII dominating at higher temperatures (the percentages of each branch to the total energy production do not have to be Sun-like as long as you get a sensible temperature scaling).

(Note that it is not necessary for your convection zone to end at the parameter values you chose in project 1. It could of course be a good starting point, but most likely you will have to change the parameters to get a wide enough convection zone, which is more important.)

**Initial parameters**

Begin with the actual values of the solar surface (except $P$, which will again differ because we are assuming an ideal gas). $\bar{\rho}$ is again the *average* density of the Sun: $\bar{\rho} = 1.408 \cdot 10^3$ kg m$^{-3}$.

\[
\begin{align*}
L_0 &= 1.0 \cdot L_{\odot} \\
R_0 &= 1.0 \cdot R_{\odot} \\
M_0 &= 1.0 \cdot M_{\odot} \\
\rho_0 &= 1.42 \cdot 10^{-7} \cdot \bar{\rho}_{\odot} \\
T_0 &= 5770 \text{ K} \\
X &= 0.7 \\
Y &= 0.29 \\
Y_3 &= 10^{-10} \\
Z &= 0.01 \\
Z_{\text{Li}} &= 10^{-13} \\
Z_{\text{Be}} &= 10^{-13}
\end{align*}
\]

It should be possible to find a solution with no parameter changing more than a factor of 5 (i.e. from $\frac{1}{5}$ to 5 times the value in the table).

This time, there is an exception: You may change $\rho_0$ as much as you want (within reason - starting at a million times the average density is unlikely to produce anything realistic).

You still may not change the element fractions $X, Y, Z$, mass $M_0$ nor luminosity $L_0$.  

---

$Id: term12.tex,v 1.10 2016/04/26 18:30:21 boris Exp$
Tasks

• If you had problems solving the first term project, please contact me, so we can find a solution.

• Solve Exerc. 5.11–5.13 (these should go into your report). These will give you an expression for the convective flux, and through that get the temperature gradient.

• You should use the model you have already done, but now include a check at each mass shell of convective stability.

• In case the shell is not convectively stable, you need to use the $\frac{\partial T}{\partial m}$ equation for convective transport instead of radiative transport (see Exerc. 5.13).

• (Optional.) If you are not using Python, you may have to implement your own cubic equation solver.\(^2\) See `cubic.pdf` on the course website for details on how to do this.

• Create the plots you will need (see “Sanity checks” and “Report” below).

Sanity checks

Implement the sanity check in example 5.1 (p.57) and see that you get values close to the ones presented there (use the actual $\mu$ calculated by your code - it should be close to 0.6).

Using the given initial conditions (before you start changing parameters), you should get a temperature gradient plot looking like this:

\(^2\)Of course, if you absolutely want to, you can do so in Python as well, but in that case, I recommend saving this for last (after finishing your report) and using the built-in solver until then, so you don’t miss the deadline.
APPENDIX E. MODELLING A STAR

and the cross-section of your star should look like this (note the empty space in the middle since $r$ does not reach 0 in this case):

The report

You are required to write a report in this exercise - writing down the method you use and in which order you solve the equations, etc. You also need to include what problems and what you have found out while solving this
exercise, this includes both numerical problems, resolution problems and problems with the physics. The report needs to be well structured and understandable. The way your report is written does impact the number of points you will get for this project.

The report has to include a printout of the code as well as a file with your code so that it can be run on a non-MS Windows machine and any licenses required must be available at the Institute of Theoretical Astrophysics. Your code will have to be written so that not only yourself can read it, and it will have to be commented, meaning that when defining a variable or constant, it has to be explained as well as when calculating something that will have to explained as well. The code should be structured logically so that it is easily understandable. This is a very important point - if I do not understand what happens in the code, it will mean a serious deduction in the number of points you will get - even if you successfully solve it!

There will be no extensions to the deadline, except in case of documented medical circumstances. If you cannot solve it, write the report anyway, explaining your problems and what you tried in order to solve them.

Your report should contain the following:

• Your solutions to Exerc. 5.11–5.13 (you need not refer to them by exercise number)

• Comment on which of the initial parameters you need to change to create wider convection zone in your star. Give examples and use plots to support your claims.
  - Hint: Think back to project 1: Which parameter was critical to get right for \( \rho \) and \( r \) to converge in a way that gives you a large enough core? Does that parameter affect the amount of convection? (The expression for \( \nabla_{\text{rad}} \) contains useful information about which parameters affect convection.)

• From your final, best model include plots of the following:
  - All 5 main parameters (\( L, m, P, \rho \) and \( T \)) plotted as functions of radius (use a logarithmic axis for \( \rho \) and \( P \)).
  - The fractions of the energy being transported by convection and radiation, respectively, both as a function of radius (in the same plot).
  - The (relative) energy production from each the two branches of the PP chain as a function of radius. Overplot \( \varepsilon(r)/\varepsilon_{\text{max}} \) so you
can estimate how much each branch contributes to the overall luminosity.

- $\nabla$, $\nabla_{\text{rad}}$ and $\nabla_{\text{ad}}$ as functions of radius (include a magnified plot inside the outer convection zone so it is more clear what happens inside). Use a logarithmic axis for the $\nabla$s.

- A cross-section of your star, using coloured circles with no fill and the following colour codes (NOTE: Only draw a circle for every 50 steps or so, or your program will slow down when the plot is shown - as a bonus you will get a beautiful view of how your step size changes throughout the star). See cross-section.py on the course web page for how to do this in Python.
  * Red: Outside core ($L \geq 0.995 L_{\odot}$) and convection ($F_C > 0$).
  * Yellow: Outside core ($L \geq 0.995 L_{\odot}$) and radiation ($F_C = 0$).
  * Blue: Inside core ($L < 0.995 L_{\odot}$) and radiation ($F_C = 0$).
  * Cyan: Inside core ($L < 0.995 L_{\odot}$) and convection ($F_C > 0$).

- Compare the cross-section of your model to a cross-section of the actual Sun. What is similar? What is different?
Appendix F

Acknowledgements

The acknowledgements here are in no way complete. I should thank the students who have been exposed to the continuous development of these course notes over several years – without discrediting or insulting me in any way. Special thanks have to go to Odd Petter Sand who in 2015 rewrote the term projects 1 and 2 and created the sanity checks. Thanks also to Lars Frogner (student in the 2016 course) who found a critical mistake in the definition of $R$ in the opacity table used in "Modelling a stellar core".

Finally a thank you to Alex Ho and Lars Frogner for great help defining and producing the numerical exercise that became the exam for 2017.
