

Chapter 1

Scanning

Course “Compiler Construction”

Martin Steffen

Spring 2018

Chapter 1

Learning Targets of Chapter “Scanning”.

1. alphabets, languages,
2. regular expressions
3. finite state automata / recognizers
4. connection between the two concepts
5. minimization

The material corresponds roughly to [1, Section 2.1–2.5] or a large part of [3, Chapter 2]. The material is pretty canonical anyway.

Chapter 1

Scanner section overview

INF5110 –
Compiler
Construction

What's a scanner?

- Input: source code.¹
 - Output: sequential stream of **tokens**
-
- *regular expressions* to describe various token classes
 - (deterministic/non-deterministic) finite-state automata (FSA, DFA, NFA)
 - implementation of FSA
 - regular expressions → NFA
 - NFA ↔ DFA

¹The argument of a scanner is often a *file name* or an *input stream* or similar.

What's a scanner?

- other names: lexical scanner, **lexer**, tokenizer

A scanner's functionality

Part of a compiler that takes the source code as input and translates this stream of characters into a stream of **tokens**.

- char's typically language independent.²
- tokens** already language-specific.³
- works always “left-to-right”, producing one *single token* after the other, as it scans the input⁴
- it “segments” char stream into “chunks” while at the same time “classifying” those pieces ⇒ **tokens**

²Characters are language-independent, but perhaps the encoding (or its interpretation) may vary, like ASCII, UTF-8, also Windows-vs.-Unix-vs.-Mac newlines etc.

³There are large commonalities across many languages, though.

⁴No theoretical necessity, but that's how also humans consume or “scan” a source-code text. At least those humans trained in e.g. Western languages.

Typical responsibilities of a scanner

- segment & classify char stream into tokens
- typically described by “rules” (and **regular expressions**)
- typical language aspects covered by the scanner
 - describing *reserved words* or *key words*
 - describing format of *identifiers* (= “strings” representing variables, classes ...)
 - comments (for instance, between // and NEWLINE)
 - *white space*
 - to segment into tokens, a scanner typically “jumps over” white spaces and afterwards starts to determine a new token
 - not only “blank” character, also TAB, NEWLINE, etc.
- lexical rules: often (explicit or implicit) *priorities*
 - *identifier* or *keyword*? ⇒ keyword
 - take the *longest* possible scan that yields a valid token.

“Scanner = regular expressions (+ priorities)”

Rule of thumb

Everything about the source code which is so simple that it can be captured by **reg. expressions** belongs into the scanner.

How does scanning roughly work?

- usual invariant in such pictures (by convention): arrow or head points to the *first* character to be *read next* (and thus *after* the last character having been scanned/read last)
- in the scanner *program* or procedure:
 - analogous invariant, the arrow corresponds to a *specific variable*
 - contains/points to the next character to be read
 - name of the variable depends on the scanner/scanner tool
- the *head* in the pic: for illustration, the scanner does not really have a “reading head”
 - remembrance of Turing machines, or
 - the old times when perhaps the program data was stored on a tape.⁵

⁵Very deep down, if one still has a magnetic disk (as opposed to SSD) the secondary storage still has “magnetic heads”, only that one typically does not parse *directly* char by char from disk. . .

The bad(?) old times: Fortran

- in the days of the pioneers
- main memory was *smaaaaaaaaaaall*
- compiler technology was not well-developed (or not at all)
- programming was for *very* few “experts”.⁶
- Fortran was considered very high-level (wow, a language so complex that you had to compile it . . .)

⁶There was no computer science as profession or university curriculum.

(Slightly weird) lexical aspects of Fortran

INF5110 –
Compiler
Construction

Lexical aspects = those dealt with a scanner

- **whitespace** *without* “meaning”:

```
I F ( X 2.   EQ. 0) TH E N vs. IF ( X2.
                    EQ.0 ) THEN
```

- no **reserved** words!

```
IF (IF.EQ.0) THEN THEN=1.0
```

- general *obscurity* tolerated:

```
DO99I=1,10 vs. DO99I=1.10
```

```
DO 99 I=1,10
-
-
99 CONTINUE
```

Fortran scanning: remarks

- Fortran (of course) has evolved from the pioneer days
...
- no keywords: nowadays mostly seen as *bad* idea⁷
- treatment of white-space as in Fortran: not done anymore: THEN and TH EN *are* different things in all languages
- however:⁸ both considered “the same”:

```
if b then ..
```

```
if    b then ..
```

- since concepts/tools (and much memory) were missing, Fortran scanner and parser (and compiler) were
 - quite simplistic
 - syntax: designed to “help” the lexer (and other phases)

⁷It's mostly a question of language *pragmatics*. Lexers/parsers would have no problems using `while` as variable, but humans tend to.

⁸Sometimes, the part of a lexer / parser which removes whitespace (and comments) is considered as separate and then called *screeener*. Not

INF5110 –

implementations
and scanner
generation tools

A scanner classifies

- “good” classification: depends also on later phases, may not be clear till later

Rule of thumb

Things being treated equal in the syntactic analysis (= parser, i.e., subsequent phase) should be put into the same category.

- terminology not 100% uniform, but most would agree:

Lexemes and tokens

Lexemes are the “chunks” (pieces) the scanner produces from segmenting the input source code (and typically dropping whitespace). **Tokens** are the result of *classifying* those lexemes.

- token = token name × token value

INF5110 –

Determinization

Minimization

Scanner
implementations
and scanner
generation tools

A scanner classifies & does a bit more

- token data structure in *OO* settings
 - token themselves defined by classes (i.e., as instance of a class representing a specific token)
 - token values: as attribute (instance variable) in its values
- often: scanner does slightly *more* than just classification
 - store names in some *table* and store a corresponding index as attribute
 - store text constants in some *table*, and store corresponding index as attribute
 - even: *calculate* numeric constants and store value as attribute

INF5110 –

One possible classification

name/identifier	abc123
integer constant	42
real number constant	3.14E3
text constant, string literal	"this is a text constant"
arithmetic op's	+ - * /
boolean/logical op's	and or not (alternatively /\ \/)
relational symbols	<= < >= > = == !=

all other tokens: { } () [] , ; := . etc.

every one it its own group

- this classification: not the only possible (and not necessarily complete)
- note: *overlap*:
 - "." is here a token, but also part of real number constant
 - "<" is part of "<="

One way to represent tokens in C

INF5110 –
Compiler
Construction

```
typedef struct {  
    TokenType tokenval;  
    char * stringval;  
    int numval;  
} TokenRecord;
```

If one only wants to store one attribute:

```
typedef struct {  
    Tokentype tokenval;  
    union  
    { char * stringval;  
      int numval  
    } attribute;  
} TokenRecord;
```

How to define lexical analysis and implement a scanner?

- even for complex languages: lexical analysis (in principle) not hard to do
- “manual” implementation straightforwardly possible
- *specification* (e.g., of different token classes) may be given in “prosa”
- however: there are straightforward formalisms and efficient, rock-solid tools available:
 - easier to specify unambiguously
 - easier to communicate the lexical definitions to others
 - easier to change and maintain
- often called **parser generators** typically not just generate a scanner, but code for the next phase (parser), as well.

Regular expressions

Chapter 1 “Scanning”
Course “Compiler Construction”
Martin Steffen
Spring 2018

General concept: How to generate a scanner?

1. **regular expressions** to describe language's *lexical* aspects
 - like whitespaces, comments, keywords, format of identifiers etc.
 - often: more “user friendly” variants of reg-exprs are supported to specify that phase
2. *classify* the lexemes to tokens
3. translate the reg-expressions \Rightarrow NFA.
4. turn the NFA into a *deterministic* FSA (= DFA)
5. the DFA can straightforwardly be implemented
 - step done automatically by a “lexer generator”
 - lexer generators help also in other user-friendly ways of specifying the lexer: defining *priorities*, assuring that the longest possible token is given back, repeat the process to generate a sequence of tokens⁹

⁹Maybe even prepare useful error messages if scanning (not scanner generation) fails.

Use of regular expressions

- **regular languages**: fundamental class of “languages”
- **regular expressions**: standard way to describe regular languages
- not just used in compilers
- often used for flexible “*searching*”: simple form of **pattern matching**
- e.g. input to search engine interfaces
- also supported by many editors and text processing or scripting languages (starting from classical ones like `awk` or `sed`)
- but also tools like `grep` or `find` (or general “globbing” in shells)

```
find . -name "*.tex"
```

- often **extended** regular expressions, for user-friendliness, not theoretical expressiveness

Alphabets and languages

Definition (Alphabet Σ)

Finite set of elements called “letters” or “symbols” or “characters”.

Definition (Words and languages over Σ)

Given alphabet Σ , a **word** over Σ is a finite sequence of letters from Σ . A **language** over alphabet Σ is a *set* of finite *words* over Σ .

- in this lecture: we avoid terminology “symbols” for now, as later we deal with e.g. symbol tables, where symbols means something slightly different (at least: at a different level).
- Sometimes Σ left “implicit” (as assumed to be understood from the context)
- practical examples of alphabets: ASCII, Norwegian letters (capital and non-capitals) etc.

Languages

- note: Σ is finite, and words are of *finite* length
- languages: in general *infinite* sets of words
- simple examples: Assume $\Sigma = \{a, b\}$
- *words* as finite “sequences” of letters
 - ϵ : the empty word (= empty sequence)
 - ab means “ first a then b ”
- sample languages over Σ are
 1. $\{\}$ (also written as \emptyset) the empty set
 2. $\{a, b, ab\}$: language with 3 finite words
 3. $\{\epsilon\}$ ($\neq \emptyset$)
 4. $\{\epsilon, a, aa, aaa, \dots\}$: infinite languages, all words using only a 's.
 5. $\{\epsilon, a, ab, aba, abab, \dots\}$: alternating a 's and b 's
 6. $\{ab, bbab, aaaaa, bbabbabab, aabb, \dots\}$: ??????

How to describe languages

- language mostly here in the abstract sense just defined.
- the “dot-dot-dot” (...) is not a good way to describe to a computer (and to many humans) what is meant
- enumerating explicitly all allowed words for an infinite language does not work either

Needed

A **finite** way of describing infinite languages (which is hopefully efficiently implementable & easily readable)

Beware

Is it apriori to be expected that *all* infinite languages can even be captured in a finite manner?

- small metaphor

Regular expressions

INF5110 –
Compiler
Construction

Definition (Regular expressions)

A *regular expression* is one of the following

1. a *basic* regular expression of the form a (with $a \in \Sigma$), or ϵ , or \emptyset
2. an expression of the form $r \mid s$, where r and s are regular expressions.
3. an expression of the form rs , where r and s are regular expressions.
4. an expression of the form r^* , where r is a regular expression.

Precedence (from high to low): $*$, concatenation, $|$

Same again

Notational conventions

Later, for CF grammars, we use capital letters to denote “variables” of the grammars (then called *non-terminals*). If we like to be consistent with that convention, the definition looks as follows:

$$\begin{aligned} R &\rightarrow a \\ R &\rightarrow \epsilon \\ R &\rightarrow \emptyset \\ R &\rightarrow R \mid R \\ R &\rightarrow RR \\ R &\rightarrow R^* \end{aligned} \quad (3)$$

Symbols, meta-symbols, meta-meta-symbols . . .

- regexps: notation or “language” to describe “languages” over a given alphabet Σ (i.e. subsets of Σ^*)
 - language being described \Leftrightarrow language used to describe the language
- \Rightarrow language \Leftrightarrow meta-language
- here:
 - regular expressions: notation to describe regular languages
 - English resp. context-free notation: notation to describe regular expression
 - for now: carefully use *notational convention* for precision

Notational conventions

- notational conventions by *typographic* means (i.e., different fonts etc.)
- you need good eyes, but: difference between
 - α and a
 - ϵ and ϵ
 - \emptyset and \emptyset
 - $|$ and $|$ (especially hard to see : -)
 - ...
- later (when gotten used to it) we may take a more “relaxed” attitude toward it, assuming things are clear, as do many textbooks
- Note: in compiler *implementations*, the distinction between language and meta-language etc. is very real (even if not done by typographic means ...)

Semantics (meaning) of regular expressions

Definition (Regular expression)

Given an alphabet Σ . The meaning of a regexp r (written $\mathcal{L}(r)$) over Σ is given by equation (5).

$\mathcal{L}(\emptyset)$	$=$	$\{\}$	empty language
$\mathcal{L}(\epsilon)$	$=$	$\{\epsilon\}$	empty word
$\mathcal{L}(a)$	$=$	$\{a\}$	single “letter” from Σ
$\mathcal{L}(rs)$	$=$	$\{w_1w_2 \mid w_1 \in \mathcal{L}(r), w_2 \in \mathcal{L}(s)\}$	concatenation
$\mathcal{L}(r \mid s)$	$=$	$\mathcal{L}(r) \cup \mathcal{L}(s)$	alternative
$\mathcal{L}(r^*)$	$=$	$\mathcal{L}(r)^*$	iteration

(5)

- conventional *precedences*: $*$, concatenation, $|$.
- Note: left of “=”: reg-expr *syntax*, right of “=”: semantics/meaning/math ¹⁰

¹⁰Sometimes confusingly “the same” notation.

Examples

INF5110 –
Compiler
Construction

In the following:

- $\Sigma = \{a, b, c\}$.
- we don't bother to “boldface” the syntax

words with exactly one b
words with max. one b

$$(a|c)^*b(a|c)^*$$
$$((a|c)^*|((a|c)^*b(a|c)^*))$$
$$(a|c)^*(b|\epsilon)(a|c)^*$$

words of the form $a^nb a^n$,
i.e., equal number of a 's
before and after 1 b

Martin Steffen
Spring 2018

Finite-state automata

- simple “computational” machine
- (variations of) FSA’s exist in many flavors and under different names
- other rather well-known names include finite-state machines, finite labelled transition systems,
- “state-and-transition” representations of programs or behaviors (finite state or else) are wide-spread as well
 - state diagrams
 - Kripke-structures
 - I/O automata
 - Moore & Mealy machines
- the logical behavior of certain classes of electronic circuitry with internal memory (“flip-flops”) is described by finite-state automata.

Definition (FSA)

A FSA \mathcal{A} over an alphabet Σ is a tuple $(\Sigma, Q, I, F, \delta)$

- Q : finite set of states
- $I \subseteq Q, F \subseteq Q$: initial and final states.
- $\delta \subseteq Q \times \Sigma \times Q$ transition relation
- final states: also called *accepting* states
- transition relation: can *equivalently* be seen as function $\delta : Q \times \Sigma \rightarrow 2^Q$: for each state and for each letter, give back the *set* of successor states (which may be empty)
- more suggestive notation: $q_1 \xrightarrow{a} q_2$ for $(q_1, a, q_2) \in \delta$
- we also use freely —self-evident, we hope— things like

$$q_1 \xrightarrow{a} q_2 \xrightarrow{b} q_3$$

FSA as scanning machine?

- FSA have slightly unpleasant properties when considering them as describing an actual program (i.e., a scanner procedure/lexer)
- given the “theoretical definition” of acceptance:

Mental picture of a scanning automaton

The automaton eats one character after the other, and, when reading a letter, it moves to a successor state, if any, of the current state, depending on the character at hand.

- 2 problematic aspects of FSA
 - **non-determinism**: what if there is more than one possible successor state?
 - **undefinedness**: what happens if there's no next state for a given input
- the 2nd one is *easily* repaired, the 1st one requires more thought
- [1]: **recogniser** corresponds to DFA

DFA: deterministic automata

INF5110 –
Compiler
Construction

Definition (DFA)

A *deterministic, finite automaton* \mathcal{A} (DFA for short) over an alphabet Σ is a tuple $(\Sigma, Q, I, F, \delta)$

- Q : finite set of states
 - $I = \{i\} \subseteq Q$, $F \subseteq Q$: initial and final states.
 - $\delta: Q \times \Sigma \rightarrow Q$ transition function
-
- transition function: special case of transition relation:
 - deterministic
 - left-total (“complete”)

Meaning of an FSA

INF5110 –
Compiler
Construction

Semantics

The intended **meaning** of an FSA over an alphabet Σ is the set of all the finite words, the automaton **accepts**.

Definition (Accepting words and language of an automaton)

A word $c_1c_2 \dots c_n$ with $c_i \in \Sigma$ is **accepted** by automaton \mathcal{A} over Σ , if there exists states q_0, q_2, \dots, q_n from Q such that

$$q_0 \xrightarrow{c_1} q_1 \xrightarrow{c_2} q_2 \xrightarrow{c_3} \dots q_{n-1} \xrightarrow{c_n} q_n ,$$

and were $q_0 \in I$ and $q_n \in F$. The **language** of an FSA \mathcal{A} , written $\mathcal{L}(\mathcal{A})$, is the set of all words that \mathcal{A} accepts.

Non-deterministic FSA

INF5110 –
Compiler
Construction

Definition (NFA (with ϵ transitions))

A **non-deterministic** finite-state automaton (NFA for short) \mathcal{A} over an alphabet Σ is a tuple $(\Sigma, Q, I, F, \delta)$, where

- Q : finite set of states
- $I \subseteq Q, F \subseteq Q$: initial and final states.
- $\delta: Q \times \Sigma \rightarrow 2^Q$ transition function

In case, one uses the alphabet $\Sigma + \{\epsilon\}$, one speaks about an NFA with ϵ -transitions.

- in the following: NFA mostly means, allowing ϵ transitions¹¹
- ϵ : treated *differently* than the “normal” letters from Σ .
- δ can *equivalently* be interpreted as *relation*:
 $\delta \subseteq Q \times \Sigma \times Q$ (transition relation labelled by elements from Σ).

¹¹It does not matter much anyhow, as we will see.

Language of an NFA

- remember $\mathcal{L}(\mathcal{A})$ (Definition 7 on page 42)
- applying definition directly to $\Sigma + \{\epsilon\}$: accepting words “containing” letters ϵ
- as said: *special* treatment for ϵ -transitions/ ϵ -“letters”. ϵ rather represents *absence* of input character/letter.

Definition (Acceptance with ϵ -transitions)

A word w over alphabet Σ is **accepted** by an NFA with ϵ -transitions, if there exists a word w' which is accepted by the NFA with alphabet $\Sigma + \{\epsilon\}$ according to Definition 7 and where w is w' with all occurrences of ϵ **removed**.

Alternative (but equivalent) intuition

\mathcal{A} reads one character after the other (following its transition relation). If in a state with an outgoing ϵ -transition, \mathcal{A} can move to a corresponding successor state *without* reading an input symbol.

NFA vs. DFA

- *NFA*: often easier (and smaller) to write down, esp. starting from a regular expression
- non-determinism: not *immediately* transferable to an *algo*

Regular expressions → NFA

- needed: a *systematic* translation (= algo, best an efficient one)
- conceptually easiest: translate to NFA (with ϵ -transitions)
 - postpone determinization for a second step
 - (postpone minimization for later, as well)

Compositional construction [5]

Design goal: The NFA of a compound regular expression is given by taking the NFA of the immediate subexpressions and connecting them appropriately.

- construction slightly¹² simpler, if one uses automata with **one** start and one accepting state

⇒ ample use of ϵ -transitions

¹²It does not matter much, though.

Spring 2018

Determinization: the subset construction

Main idea

- Given a non-det. automaton \mathcal{A} . To construct a DFA $\overline{\mathcal{A}}$: instead of *backtracking*: explore all successors “at the same time” \Rightarrow
- each state q' in $\overline{\mathcal{A}}$: represents a *subset* of states from \mathcal{A}
- Given a word w : “feeding” that to $\overline{\mathcal{A}}$ leads to *the* state representing *all* states of \mathcal{A} *reachable* via w

- side remark: this construction, known also as *powerset* construction, seems straightforward enough, but: analogous constructions works for some other kinds of automata, as well, but for others, the approach does *not* work.¹³
- origin: [4]

¹³For some forms of automata, non-deterministic versions are strictly more expressive than the deterministic one.

Some notation/definitions

INF5110 –
Compiler
Construction

Definition (ϵ -closure, a -successors)

Given a state q , the ϵ -closure of q , written $close_\epsilon(q)$, is the set of states reachable via zero, one, or more ϵ -transitions. We write q_a for the set of states, reachable from q with one a -transition. Both definitions are used analogously for sets of states.

Transformation process: sketch of the algo

Input: NFA \mathcal{A} over a given Σ

Output: DFA $\overline{\mathcal{A}}$

1. the *initial* state: $close_{\epsilon}(I)$, where I are the initial states of $\overline{\mathcal{A}}$
2. for a state Q' in $\overline{\mathcal{A}}$: the *a-successor* of Q is given by $close_{\epsilon}(Q_a)$, i.e.,

$$Q \xrightarrow{a} close_{\epsilon}(Q_a) \quad (11)$$

3. repeat step 2 for all states in $\overline{\mathcal{A}}$ and all $a \in \Sigma$, until no more states are being added
4. the *accepting* states in $\overline{\mathcal{A}}$: those containing *at least* one accepting state of \mathcal{A}

Note: [1]: slightly more “concrete” formulation using a work-list.

Spring 2018

Minimization

- automatic construction of DFA (via e.g. Thompson): often many superfluous states
- goal: “combine” states of a DFA without changing the accepted language

Properties of the minimization algo

Canonicity: all DFA for the same language are transformed to the *same* DFA

Minimality: resulting DFA has *minimal* number of states

- “side effects”: answers to *equivalence* problems
 - given 2 DFA: do they accept the same language?
 - given 2 regular expressions, do they describe the same language?
- modern version: [2].

Hopcroft's partition refinement algo for minimization

- starting point: *complete* DFA (i.e., *error*-state possibly needed)
- first idea: *equivalent* states in the given DFA may be *identified*
- **equivalent**: when used as starting point, accepting the same language
- **partition refinement**:
 - works “the other way around”
 - instead of collapsing equivalent states:
 - start by “collapsing as much as possible” and then,
 - iteratively, detect *non-equivalent* states, and then *split* a “collapsed” state
 - stop when no violations of “equivalence” are detected
- *partitioning* of a set (of states):
- *worklist*: data structure of to keep non-treated classes, termination if worklist is empty

Scanner
implementations
and scanner
generation tools

Partition refinement: a bit more concrete

- **Initial** partitioning: 2 partitions: set containing all *accepting* states F , set containing all *non-accepting* states $Q \setminus F$
- **Loop** do the following: pick a current equivalence class Q_i and a symbol a
 - if for all $q \in Q_i$, $\delta(q, a)$ is member of the *same* class Q_j
 \Rightarrow consider Q_i as done (for now)
 - else:
 - **split** Q_i into Q_i^1, \dots, Q_i^k s.t. the above situation is repaired for each Q_i^l (but don't split more than necessary).
 - be aware: a split may have a “cascading effect”: other classes being fine before the split of Q_i need to be reconsidered \Rightarrow *worklist* algo
- **stop** if the situation stabilizes, i.e., no more split happens (= worklist empty, at latest if back to the original DFA)

Scanner implementations and scanner generation tools

Chapter 1 “Scanning”
Course “Compiler Construction”
Martin Steffen
Spring 2018

Tools for generating scanners

- scanners: simple and well-understood part of compiler
- hand-coding possible
- mostly better off with: generated scanner
- standard tools *lex* / *flex* (also in combination with *parser* generators, like *yacc* / *bison*)
- variants exist for many implementing languages
- based on the results of this section

Main idea of (f)lex and similar

- output of lexer/scanner = input for parser
- programmer specifies regular expressions for each **token**-class and corresponding actions¹⁴ (and whitespace, comments etc.)
- the spec. language offers some conveniences (extended regexr with priorities, associativities etc) to ease the task
- automatically translated to NFA (e.g. Thompson)
- then made into a deterministic DFA (“subset construction”)
- minimized (with a little care to keep the token classes separate)
- implement the DFA (usually with the help of a *table* representation)

¹⁴ Tokens and actions of a parser will be covered later. For example, identifiers and digits as described but the reg. expressions, would end up in two different token classes, where the actual string of characters (also known as *lexeme*) being the value of the token attribute.

Targets & Outline

Intro

Regular expressions

DFA

Implementation of DFA

NFA

From regular expressions to DFAs (Thompson's construction)

Determinization

Minimization

Scanner implementations and scanner generation tools
